APPENDIX G.1 – TECHNICAL EVALUATION OF GEOTECHNICAL AND CCR MATERIAL CHARACTERISTICS DATA

Introduction
March 12, 2024

1.0 INTRODUCTION

Stantec Consulting Services Inc. (Stantec), on behalf of the Tennessee Valley Authority (TVA), has prepared this technical evaluation appendix to summarize applicable historical and recent geotechnical information and coal combustion residuals (CCR) material characteristics data at TVA's Kingston Fossil Plant (KIF Plant) in Harriman, Tennessee. This appendix provides a detailed evaluation of these data to support information provided in the Environmental Assessment Report (EAR) to fulfil the requirements for the Tennessee Department of Environment and Conservation (TDEC) Commissioner's Order OGC15-0177 (TDEC Order) Program (TDEC 2015).

2.0 GEOTECHNICAL INVESTIGATION

The purpose of the geotechnical investigation was to further characterize and evaluate subsurface conditions for the three TDEC Order CCR management units[1] at the KIF Plant, which include the Stilling Pond, Interim Ash Staging Area, and Sluice Trench and Area East of Sluice Trench. For this investigation, TVA reviewed information from previous representative studies and assessments, completed an exploratory drilling (EXD) field program, and conducted evaluations for slope stability, structural integrity, and structural stability (bedrock) as part of the TDEC Order Environmental Investigation (EI).

The following sections summarize the previous studies and present overall geotechnical investigation and evaluation findings based on data obtained during previous studies and the EI for the KIF Plant TDEC Order CCR management units. Elevations reported herein are referenced to the National Geodetic Vertical Datum of 1929 (NGVD29).

2.1 EXPLORATORY DRILLING

2.1.1 Previous Representative Studies and Assessments

Through the various information requests, as well as TDEC comments on the *Environmental Investigation Plan* (EIP) (TVA 2018), a need was identified for an evaluation of existing geotechnical data (borings, piezometric data, laboratory data, material parameters, analyses, etc.). The Evaluation of Existing Geotechnical Data (Appendix L of the EIP) was prepared to review the existing (at the time the EIP was written) data and evaluate its adequacy for responding to the various information requests. Evaluating the adequacy of existing data, in accordance with the *Quality Assurance Project Plan (QAPP)* (Environmental Standards Inc. [EnvStds] 2018), depends on both the type of data and its intended use. Where applicable, existing geotechnical data were used to support the subjects addressed throughout the EAR.

Stilling Pond

From 1975 to 2019, several geotechnical explorations were performed at the Stilling Pond for various objectives. Over 80 borings were performed, some of which included rock coring, monitoring well installation, or piezometer installation. Geotechnical laboratory testing was often performed on recovered soil samples. Cone penetration tests (CPTs) were also performed along portions of the unit perimeter. As would be expected for an impoundment, most of the previous boring locations were focused on the perimeter of the unit (particularly adjacent to Kingston Recovery Project (KRP) Ash Landfill) because they were often related to perimeter dike and/or the KRP Ash Landfill slope design, construction, seepage assessment, slope stability assessment, and/or performance monitoring. Boring locations are shown on Exhibit G.1-1. Refer to the Evaluation of Existing Geotechnical Data (Appendix L in the EIP; Stantec 2018a) for more detailed descriptions of the individual explorations, including evaluations of their adequacy for responding to the various information requests.

[1] The term “CCR management unit” is used in this document generally and is not intended to be a designation under federal or state regulations.

Interim Ash Staging Area

From 2009 to 2016, several geotechnical explorations were performed at the Interim Ash Staging Area for various objectives. Over 50 borings were performed, some of which included rock coring, monitoring well installation, or piezometer installation. Geotechnical laboratory testing was often performed on recovered soil samples. CPTs were also performed within the interior of the unit and along portions of the unit perimeter. Most of the previous boring locations were focused on the perimeter of the unit, particularly adjacent to the KRP Ash Landfill (related to perimeter dike and/or the landfill slope design and construction) and within the footprint of the Bottom Ash Dewatering Facility (related to structure foundation design). Boring locations are shown on Exhibit G.1-1. Refer to the Evaluation of Existing Geotechnical Data (Appendix L in the EIP; Stantec 2018a) for more detailed descriptions of the individual explorations, including evaluations of their adequacy for responding to the various information requests.

Sluice Trench and Area East of Sluice Trench

Between 2009 and 2015, several geotechnical explorations were performed at the Sluice Trench and Area East of Sluice Trench for various objectives. Approximately 20 borings were performed, some of which included rock coring or piezometer installation. Geotechnical laboratory testing was often performed on recovered soil samples. CPTs were also performed within the interior of the unit and along portions of the unit perimeter. As would be expected for a unit that was originally part of an impoundment, most of the previous boring locations were focused on the perimeter of the unit, particularly adjacent to the Intake Channel, because they were often related to perimeter dike and/or the slope design, construction, seepage assessment, slope stability assessment, and/or performance monitoring. Boring locations are shown on Exhibit G.1-1. Refer to the Evaluation of Existing Geotechnical Data (Appendix L in the EIP; Stantec 2018a) for more detailed descriptions of the individual explorations, including evaluations of their adequacy for responding to the various information requests.

2.1.2 TDEC Order Environmental Investigation Activities

Objectives and Scope

EXD field work was conducted in two phases (Phase 1 and Phase 2) and consisted of three primary activities – drilling and sampling, installing temporary wells, and installing piezometers. The primary objective of the Phase 1 EXD, conducted pursuant to the *EXD Sampling and Analysis Plan* (SAP) (Stantec 2018b), was to perform borings and install temporary wells to further characterize subsurface conditions at the KIF Plant, in response to the TDEC Order. The EXD SAP included activities at two CCR units: Interim Ash Staging Area and Sluice Trench and Area East of Sluice Trench. The primary objective of the Phase 2 EXD, conducted pursuant to the *Addendum to Exploratory Drilling SAP* (EXD SAP Addendum) (Stantec 2020a), was to perform borings and install vibrating wire piezometers to further characterize subsurface conditions at the KIF Plant, in response to the TDEC Order. The EXD SAP Addendum included activities at one CCR unit: Sluice Trench and Area East of Sluice Trench.

EI field activities were performed in general accordance with the EXD SAP, EXD SAP Addendum, and the *QAPP,* including TVA- and TDEC-approved programmatic and project-specific changes made after approval of the EIP. Exploration location selection, collection methodology, analyses, and quality assurance/quality control completed for the investigation are provided in the *EXD Sampling and Analysis Report* (SAR) included in Appendix G.2.

The scope of work of the Phase 1 EXD consisted of the following tasks:

- Drilling borings
- Collecting disturbed and undisturbed soil samples for lithologic information
- Installing temporary wells, constructing surface protections, and developing the wells
- Conducting slug tests in temporary wells
- Performing geotechnical laboratory testing
- Surveying boring and temporary well locations.

The scope of work of the Phase 2 EXD consisted of the following tasks:

- Drilling borings
- Collecting disturbed and undisturbed soil samples for lithologic information
- Installing vibrating wire piezometers (VWPs)
- Performing geotechnical laboratory testing
- Surveying boring locations.

Boring locations are shown on Exhibits G.1-2 and G.1-3. For additional details on the objectives and scope, refer to the EXD SAR provided as Appendix G.2.

2.1.3 Results

Stilling Pond

No Phase 1 or Phase 2 EXD borings were performed at the Stilling Pond.

Interim Ash Staging Area

During the Phase 1 EXD, five temporary well borings and six direct push borings were drilled in the interior of the Interim Ash Staging Area. Temporary wells were installed above the base of CCR materials in three of the temporary well borings. After the completion of drilling and laboratory testing of samples from the temporary well borings, review of the data showed that three of these borings were inadvertently terminated within CCR material. Therefore, the supplemental direct push borings were added to extend the material profiles into the foundation soils and obtain the deeper samples adjacent to the installed temporary wells. Two direct push borings were advanced adjacent to each temporary well. The uppermost foundation soil was lean clay (CL) in four of the direct push borings and silty sand (SM) in the remaining two direct push borings.

No Phase 2 EXD borings were performed at the Interim Ash Staging Area.

Sluice Trench and Area East of Sluice Trench

During the Phase 1 EXD, two temporary well borings and one direct push boring were drilled within the interior of the Sluice Trench and Area East of Sluice Trench. Temporary wells were installed above the base of CCR materials in each temporary well boring. After the completion of drilling and laboratory testing of samples from the temporary well borings, review of the data showed that one of these borings was inadvertently terminated within CCR material. Therefore, a supplemental direct push boring was added to extend the material profile into the foundation soils and obtain the deeper samples adjacent to the installed temporary well. The uppermost foundation soil was CL in the two borings.

During the Phase 2 EXD, 12 geotechnical borings, including three with VWPs were performed at the Sluice Trench and Area East of Sluice Trench. The borings were drilled to collect geotechnical data and to support seismic stability analysis (Exhibit G.1-3). Three borings were located along the crest of the East Dike. The remaining nine borings were located along or near the outboard toe of the East Dike. The uppermost foundation soil was CL in five borings and silt (ML) in the remaining seven borings.

2.1.4 Discussion

Stantec completed the EXD at the KIF Plant in accordance with the EXD SAP and EXD SAP Addendum as documented in the EXD SAR. The data collected during the EXD are usable for reporting and evaluation in the EAR and meet the objectives of the TDEC Order EIP.

At each boring location, the uppermost foundation soil was predominantly lean clay (11 occurrences), with lesser occurrences of silt (seven occurrences) or silty sand (two occurrences). This is generally consistent with historical borings across the TDEC Order CCR management units. For more information on CCR management unit performance, refer to Section 2.2 regarding slope stability, Section 3.1.4 and Appendix H.1 regarding groundwater and pore water flow, and EAR Chapter 4.3 for material quantity modeling.

2.2 SLOPE STABILITY

The load cases evaluated in the stability analyses are based on conventional practice and appropriate industry standards for landfills and surface impoundments, as applicable. The load cases are as follows:

- Static, long-term (i.e., normal operation conditions) global stability
- Static, long-term veneer (i.e., final cover) stability
- Seismic, pseudostatic global stability
- Seismic, pseudostatic veneer stability
- Seismic, post-earthquake global stability (includes a preceding liquefaction triggering assessment).

As described in the EIP, including the Evaluation of Existing Geotechnical Data (Appendix L of the EIP; Stantec 2018a), the existing data are sufficient to establish appropriate shear strengths and stability results for certain static and seismic load cases. Supplemental geotechnical data were collected, per the EXD SAP (Stantec 2018b), to support the new or updated stability analyses described in the EIP and the Stability SAP (Stantec 2018c). The new or updated stability analyses also utilize the existing data noted above. The summaries of existing geotechnical data demonstrate that those data are representative and suitable to support the new or updated stability analyses. For the KIF Plant, the Stability SAP (with scope updates as documented in the *Static Stability SAR* and *Seismic Stability SAR*) was necessary to address:

1) the Sluice Trench and Area East of Sluice Trench static global, static veneer, seismic global, and seismic veneer slope stability analyses for the current, closed geometry.

2.2.1 Previous Representative Studies and Assessments

Through the various information requests, as well as TDEC comments on the EIP, a need was identified for an evaluation of existing slope stability analyses (geometry, pore water pressures, material parameters, seismic inputs, analysis methods, results, etc.). As an appendix of the EIP (Appendix L), the Evaluation of Existing Geotechnical Data (Stantec 2018a) was prepared to review the existing analyses and evaluate their adequacy with respect to responding to the various information requests. Evaluating the adequacy of existing data depends on both the type of data and its use. Where applicable, existing geotechnical data were used to support the subjects addressed throughout the EAR. For a summary of historical slope stability analyses utilized to address the required load cases, see Tables G.1-1 and G.1-2 in Section 2.2.3.

As described in the Evaluation of Existing Geotechnical Data (Appendix L of the EIP; Stantec 2018a), existing data (if available) that were considered for evaluating stability of the waste fill and side-slope berms included:

- Slope stability analyses of existing conditions

- Slope stability analyses of future (i.e., permitted, “build-out”, or closed) conditions
- Structural stability assessments performed for CCR Rule compliance.

For stability of the waste fill and side-slope berms, the basis for evaluating the adequacy of each type of data listed above was similar:

- Representative coverage with stability analysis cross sections
- Representative cross section geometry and subsurface characterization
- Representative material parameters and phreatic conditions
- Representative loads (static loads, seismic loads, etc.)
- Appropriate stability analysis methods
- Potential for relevant changes in conditions since analyses were performed.

For evaluating CCR and soil material parameters, including shear strengths, existing data (if available) that were considered included:

- Parameters based on *in situ* testing
- Parameters based on laboratory testing
- Parameters based on published values for similar materials.

For evaluating CCR and soil material parameters, the basis for evaluating the adequacy of each type of data listed above was similar:

- Locations of *in situ* tests and/or samples for each material
- Suitability of methods used to perform *in situ* testing, to collect samples, and to perform laboratory testing. Suitability is judged qualitatively, based on how well the methods obtain the necessary data and compare to the current standard of practice.
- Potential for relevant changes in subsurface conditions since *in situ* testing and/or sampling were performed.

Stilling Pond

TVA performed a static, global safety factor assessment (Stantec 2017a) for the Stilling Pond. Based on recent geotechnical explorations and topographic survey data, two critical cross sections (Station 119+69 and 132+37) were developed for slope stability analysis. Static, global slope stability was analyzed for long-term, drained conditions (normal pool). The assessment also evaluated shallow, translational (veneer-type) stability of the final cover system for static drained and seismic loading conditions. The global slope stability analyses were focused on the potential for outslope failures of significant mass,

which could directly influence potential release of CCR materials from the Stilling Pond. Based upon these analysis results, the closed impoundment meets the minimum Factor of Safety (FS) required for static global stability, static veneer stability, and seismic pseudostatic veneer stability.

TVA performed a seismic, global safety factor assessment (Stantec 2020b) for the Stilling Pond. One critical cross section (Station 132+37) was developed for slope stability analysis. This cross section had been developed previously based on a subsurface exploration and laboratory testing by Stantec (2017a) and was updated based on subsequent geotechnical explorations and laboratory testing. Seismic, global slope stability was analyzed for long-term, drained conditions (normal pool). The seismic analyses included the seismic FS (i.e., pseudostatic slope stability) and liquefaction FS (i.e., post-earthquake slope stability, considering liquefaction). To develop the seismic loading, a site-specific seismic study was conducted based upon the design response spectra developed for the KRP Ash Landfill design. The minimum FS correspond to slip surfaces that could potentially result in the release of CCR materials from within the impoundment. Based upon the analysis performed for the Stilling Pond, the closed impoundment meets the FS criteria for both seismic FS and liquefaction FS.

Interim Ash Staging Area

The closure design of the Interim Ash Staging Area (AECOM 2016a and 2016b) generally leveled the site to conform to the surrounding grades, with gentle slopes (3 percent [%] maximum) and small perimeter ditches to promote surface drainage. Due to the higher surrounding grade, flat closure grading, and containment toward the east by the Polishing Pond, the closure documents demonstrate adequate performance of the CCR containment area without the need for static or seismic slope stability calculations. This rationale was presented in the EIP and Stability SAP and was accepted by TDEC.

Sluice Trench and Area East of Sluice Trench

No previous representative studies or assessments were available for Sluice Trench and Area East of Sluice Trench static and seismic slope stability analyses for the current, closed geometry.

2.2.2 TDEC Order Environmental Investigation Activities

Objectives and Scope

The primary objective of the static and seismic stability work, conducted pursuant to the Stability SAP (Stantec 2018c), was to develop slope stability models, including material parameters, and perform stability analyses for select CCR management units at the KIF Plant, in response to the TDEC Order.

Regarding static stability, the Stability SAP included slope stability models and static, global analyses at the Sluice Trench and Area East of Sluice Trench. The Stability SAP also included static, veneer stability analyses at the Sluice Trench and Area East of Sluice Trench. The Stability SAP did not require static stability analyses at the Stilling Pond or Interim Ash Staging Area.

Regarding seismic stability, the Stability SAP included slope stability models and seismic, global analyses (pseudostatic and post-earthquake) at the Sluice Trench and Area East of Sluice Trench. The Stability

SAP also included seismic, veneer stability analyses (pseudostatic) at a typical cross section at the Sluice Trench and Area East of Sluice Trench. The Stability SAP did not require seismic stability analyses at the Stilling Pond or Interim Ash Staging Area.

For additional details on the objectives and scope, refer to the *Static Stability SAR* and *Seismic Stability SAR* provided as Appendix G.3 and G.4, respectively.

2.2.3 Results

The global stability results presented (and compared to the acceptance criteria) are those in which the critical failure surface intercepts the contained CCR materials within the CCR management unit (unless otherwise noted). The global stability analysis models and critical failure surfaces are shown in the referenced historical documents, *Static Stability SAR* or *Seismic Stability SAR* (as applicable). Likewise, calculations for the veneer stability results presented below are included in the referenced historical documents, *Static Stability SAR* or *Seismic Stability SAR* (as applicable).

Static Stability

The static, long-term, global stability was analyzed for each cross section listed in Table G.1-1. The cross section locations for these global stability analyses are shown on Exhibit G.1-4. The static, long-term, veneer stability was analyzed for the typical geometry of the cover system (unless otherwise noted). The results of the static stability analyses, with the minimum required FS, are summarized in Table G.1-1. The static, long-term, global stability for the cross sections and the static, long-term, veneer stability for the typical sections meets the established FS criteria for the static load cases.

Table G.1-1 Long-Term, Static Stability Results at KIF Plant

TDEC Order CCR Management Unit	Analysis Type	Cross Section	FS Required	FS Sliding	Reference
Interim Ash Staging Area (Closed Condition)	Global	N/A	N/A	N/A	See discussion below
	Veneer	N/A	N/A	N/A	See discussion below
Sluice Trench and Area East of Sluice Trench (Closed Condition)	Global	A-A'	≥ 1.5	1.9	Stantec (2023a)
		Polishing Pond	≥ 1.5	2.4	Stantec (2023a)
	Veneer	Typ.	≥ 1.5	1.8	Stantec (2023a)
Stilling Pond (Closed Condition)	Global	Station 119+69	≥ 1.5	2.0	Stantec (2017a)
		Station 132+37	≥ 1.5	2.6	Stantec (2017a)
	Veneer	Typ.	≥ 1.5	1.5	Stantec (2017a)

Table G.1-1 notes that static, long-term global and veneer analyses were not applicable for the TDEC Order CCR management units. The rationale for this is as follows:

- The closure design of the Interim Ash Staging Area (AECOM 2016a and 2016b) generally leveled the site to conform to the surrounding grades, with gentle slopes (3% maximum) and small perimeter ditches to promote surface drainage. Due to the higher surrounding grade, flat closure

grading, and containment toward the east by the Polishing Pond, the closure documents demonstrate adequate performance of the CCR containment area without the need for static or seismic slope stability calculations. This rationale was presented in the EIP and Stability SAP and was accepted by TDEC.

One of the FS Sliding results presented in Table G.1-1 is for a critical failure surface that does not intercept the contained CCR materials within the CCR management unit. The static, long-term global results for cross section Station 119+69 at the Stilling Pond represents a critical failure surface in the outslope of the lower starter dike and/or rockfill buttress. Due to the geometry and material properties, the FS Sliding results for failure surfaces intercepting the contained CCR materials within the Stilling Pond would be higher (i.e., less critical) than those presented. Thus, the static, long-term, global stability for the Stilling Pond cross sections meets the established FS criteria for the static load case.

Seismic Stability

The pseudostatic, global stability and post-earthquake, global stability were analyzed for each cross section listed in Table G.1-2. The cross section locations for these global stability analyses are shown on Exhibit G.1-4. The pseudostatic, veneer stability was analyzed for the typical geometry of the cover system (unless otherwise noted). The results of the seismic stability analyses, with the minimum required FS for each case, are summarized in Table G.1-2. Seismic global and veneer analyses were not applicable for the Interim Ash Staging Area, as noted below. The pseudostatic veneer stability for the typical sections at the Sluice Trench and Area East of Sluice Trench and at the Stilling Pond meet the established FS criteria for the seismic load cases. The pseudostatic and post-earthquake, global stability for the cross sections at the Sluice Trench and Area East of Sluice Trench (both cross sections for pseudostatic, one cross section for post-earthquake) do not meet the established FS criteria for the seismic load cases and are discussed further below. The pseudostatic and post-earthquake, global stability for the cross section at the Stilling Pond meet the established FS criteria for the seismic load cases.

Table G.1-2 Seismic Stability Results at KIF Plant

TDEC Order CCR Management Unit	Analysis Type	Cross Section	FS Required	FS Sliding	Reference
Interim Ash Staging Area (Closed Condition)	Pseudostatic, Global	N/A	N/A	N/A	See discussion below
	Post-Earthquake Global	N/A	N/A	N/A	See discussion below
	Pseudostatic, Veneer	N/A	N/A	N/A	See discussion below
Sluice Trench and Area East of Sluice Trench (Closed Condition)	Pseudostatic, Global	A-A’	≥ 1.0	< 1.0 (See discussion below)	Stantec (2023b)
		Polishing Pond	≥ 1.0	< 1.0 (See discussion below)	Stantec (2023b)
	Post-Earthquake Global	A-A’	≥ 1.0	1.0	Stantec (2023b)
		Polishing Pond	≥ 1.0	0.8 (See discussion below)	Stantec (2023b)
	Pseudostatic, Veneer	Typ.	≥ 1.0	1.0	Stantec (2023b)

TDEC Order CCR Management Unit	Analysis Type	Cross Section	FS Required	FS Sliding	Reference
Stilling Pond (Closed Condition)	Pseudostatic, Global	Station 132+37	≥ 1.0	> 1.0 (See discussion below)	Stantec (2020b)
	Post-Earthquake Global	Station 132+37	≥ 1.0	1.1	Stantec (2020b)
	Pseudostatic, Veneer	Typical	≥ 1.0	1.0	Stantec (2017a)

Table G.1-2 notes that seismic global and veneer analysis were not applicable for certain CCR management units. The rationale for this is as follows:

- The closure design of the Interim Ash Staging Area (AECOM 2016a and 2016b) generally leveled the site to conform to the surrounding grades, with gentle slopes (3% maximum) and small perimeter ditches to promote surface drainage. Due to the higher surrounding grade, flat closure grading, and containment toward the east by the Polishing Pond, the closure documents demonstrate adequate performance of the CCR containment area without the need for static or seismic slope stability calculations.

The pseudostatic, global stability for the cross section at the Stilling Pond was evaluated by Stantec (2020b) using a seismic displacement analysis (i.e., Newmark analysis). The displacements due to the design earthquake were less than the tolerable displacement of three feet, and thus correlate to a FS Sliding greater than one (as defined in the Seismic Stability SAR [EAR Appendix G.4] and the Stability SAP). This meets the established FS criteria for the pseudostatic, global load case.

Instead of pursuing (per the phased approach outlined in the Stability SAP) the Phases 3 and 4 of analysis of the existing conditions, TVA has elected to pursue seismic mitigation of the Sluice Trench and Area East of Sluice Trench. TVA is currently evaluating mitigation alternatives that would be designed to meet the seismic stability acceptance criteria as defined in the Stability SAP. It is anticipated that the mitigation design process will commence in parallel with the Corrective Action/Risk Assessment (CARA) phase of the TDEC Order program.

2.2.4 Discussion

The static and seismic stability results for the KIF Plant are summarized and compared to criteria in Table G.1-1 and Table G.1-2, respectively. The global stability and the veneer stability for each analyzed section meet the established FS criteria for the static load cases. The pseudostatic veneer stability for the typical sections meet the established FS criteria for the seismic load cases. The pseudostatic and post-earthquake, global stability for the cross section at the Stilling Pond meet the established FS criteria for the seismic load cases.

The pseudostatic and post-earthquake, global stability for the cross sections at the Sluice Trench and Area East of Sluice Trench (both cross sections for pseudostatic, one cross section for post-earthquake) do not meet the established FS criteria for the seismic load cases. TVA is currently evaluating mitigation alternatives for the Sluice Trench and Area East of Sluice Trench that would be designed to meet the

seismic stability acceptance criteria as defined in the Stability SAP. It is anticipated that the mitigation design process will commence in parallel with the CARA phase of the TDEC Order program.

2.3 STRUCTURAL INTEGRITY

Per the KIF EIP, TDEC requested that TVA discuss how the structural integrity of the entire area of CCR materials disposal (surface impoundment[s], landfill(s) and non-registered sites) will be determined. Further, TVA included the methods and models in the EIP that it will use to evaluate structural integrity as discussed in 40 Code of Federal Regulations (CFR) Part 257.73(d) and (e).

For purposes of this section of the EAR, “structural integrity” considers structural potential failure modes that could lead to a release of CCR materials, other than slope stability (addressed in Section 2.2) and structural stability of bedrock (addressed in Section 2.4).

For the KIF Plant TDEC Order CCR management units, the EIP summarized historical reports that could be leveraged to address structural integrity. There was no SAR specifically required under the TDEC Order program to address this subject.

2.3.1 Previous Representative Studies and Assessments

The KIF Stilling Pond and Sluice Trench and Area East of Sluice Trench CCR management units are subject to the CCR Rule requirements for active or inactive units. While the Interim Ash Staging Area is not subject to 40 CFR Part 257.73(d) or (e), closure documents for this CCR management unit addressed many aspects of structural integrity listed in the CCR Rule 40 CFR Part 257.73(d) such as settlement, erosion protection, vegetative cover, and structural integrity of underlying hydraulic structures (AECOM 2016a). A summary of the above-mentioned studies is provided below.

TVA promotes structural integrity of the CCR management units by performing routine inspections and by evaluating proper abandonment of hydraulic structures and pipe penetrations through the unit perimeter. A summary of the structural evaluations is provided below.

Stilling Pond

The Stilling Pond is closed under a National Pollutant Discharge Elimination System (NPDES) permit and includes a final cap system of soil and geosynthetics. Final closure design of the Stilling Pond (Stantec 2017a) considered the following general design and operation issues: pool drawdown, spillway abandonment, fill placement, stormwater management system construction, final cap system installation (including establishment of vegetation cover), and access road construction.

In accordance with the CCR Rule, the Stilling Pond was closed and is monitored and maintained in accordance with a *Closure and Post-Closure Plan* (Stantec 2017c). With respect to closure, the plan summarized control of infiltration and releases, prevention of future impoundment of water, sediment, or slurry, slope stability measures, CCR management unit maintenance, drainage and stabilization of surface impoundments, and final cover system design. With respect to post-closure, the plan summarized monitoring and maintenance activities for the final cover system and groundwater monitoring system.

APPENDIX G.1 – TECHNICAL EVALUATION OF GEOTECHNICAL AND CCR MATERIAL CHARACTERISTICS DATA

Geotechnical Investigation
March 12, 2024

While closure construction was ongoing, TVA performed a structural stability assessment as required by 40 CFR Part 257.73(d) for the KIF Plant Stilling Pond surface impoundment (Stantec 2018d). The scope of work for this assessment is provided below. TVA further promotes structural integrity of the CCR management units by performing routine inspections and by evaluating proper abandonment of hydraulic structures and pipe penetrations through the unit perimeter. A summary of the structural evaluations is also provided below. Additionally, the stability program described in Section 2.2 considers the safety factor aspects of the CCR Rule, 40 CFR Part 257.73(e), such as static and seismic stability.

As part of TVA's ongoing efforts to comply with the CCR Rule, a structural stability assessment was performed for the Stilling Pond (Stantec 2018d). Within this document, "Dike C" refers to the east and southeast perimeter dike system along the Emory River and the intake channel. The "Divider Dike" refers to the dike separating the Stilling Pond from the KRP Ash Landfill. With respect to stability of the waste fill and side slope berms, this assessment considered the following aspects:

- Foundation and abutment conditions (cracking, settlement, deformation, erosion, heave due to seepage): No indications of foundation issues (i.e., cracking, settlement, depressions, and/or deformation) have been noted on historic inspection reports. Recent inspections of Dike C, performed in 2010, 2012, and 2014 note no significant signs of tension cracking, settlement, deformations or similar instabilities. In 2009 and 2010, a rock buttress consisting of filter layers and riprap armor was built on the outboard slopes along the length of Dike C. This buttress was constructed for seepage control and to improve stability of the perimeter dike system. The original spillway structure was abandoned by removing exposed piping and grouting buried piping in 2017 as part of closure construction (Stantec 2018d).

- Slope protection: The exterior slope of Dike C was armored with a riprap buttress between 2009 and 2011. The riprap buttress was inspected annually prior to the start of the closure construction, with no reported deficiencies (Stantec 2018d).

- Embankment dike compaction: Construction records related to the starter dike (built in the 1950s) and raised dike (built in the 1970s) were not available. However, TVA design drawings 31N202, 10N400, 10N420, and 10W421 provide documentation of placement and compaction requirements related to the construction of the perimeter dike. Later subsurface explorations confirm that the earth fill used for the raised portion of Dike C was appropriately compacted and that portions of the earth fill used for the original portion (starter dike) of Dike C were soft or loose. Construction criteria related to dike embankment materials and dike compaction as noted on these drawings include:

    - Portions of the starter dike embankments were placed below water. Fill was placed to the angle of repose

    - Starter dike embankments were constructed of unclassified excavation

    - Raised dike embankments were to be constructed from earth fill from approved borrow sources in accordance with standard TVA construction specifications

  - Raised dike embankments were to be compacted with sheepsfoot rollers. Connections to the starter dike were made by stripping, scarifying, and benching the surface, to provide a good bond between soil lifts.
  - For the raised dike embankments, the earth fill moisture content was to be within 3% of optimum moisture content and uniformly compacted to a minimum 95% of Standard Proctor maximum density
  - The Divider Dike was constructed of bottom ash, and the submerged portion was placed by end dumping. The above water portion was placed in lifts and was well compacted with rubber-tired hauling equipment.

- Spillway condition and capacity: The Stilling Pond closure included installation of a drainage system consisting of ditches and flumes to convey runoff to four culverts through Dike C and ultimately to the Emory River. The Inflow Design Flood Control System Plan (Stantec 2017b) documents the assessment of the Stilling Pond related to the capacity requirements outlined in §257.73(d)(1)(v) of the CCR Rule. The assessment demonstrates that the culverts located on the east perimeter of the Stilling Pond meet the capacity requirements (Stantec 2018d).
- Sudden drawdown assessment (slope stability): The exterior slope of Dike C was assessed for sudden drawdown (i.e., sudden decrease in the Emory River pool elevation) for slope failures of significant mass, which could directly impact potential release of water and CCR materials from the Stilling Pond. Based on the assessment of the sudden drawdown for Dike C, the CCR Rule-related criteria have been met.

In 2020, an annual inspection of the KIF Plant CCR Facilities was performed (TVA 2021). For the Stilling Pond, the inspection report included a general overview of site conditions, summary of areas of interest, and review of instrumentation data. The report also documented a field inspection, which included observations (as applicable) of cover soil, vegetation, drainage ditches, pipes and culverts, pumps, manholes, topography, and access roads. There were no observed deficiencies identified at the Stilling Pond during inspection that required immediate attention, monitoring, or maintenance.

In 2021, Stantec performed a cover system integrity study for the Stilling Pond, as part of CCR Rule compliance activities (Stantec 2021). The study included field inspection, document review, and instrumentation data review. The inspection included the crest of the facility, outer slopes, access roads, ditches, inlets and outlets for surface drainage, and instrumentation associated with the facilities. The inspection team did not observe any critical deficiencies or potential weaknesses in the cover system for the Stilling Pond. No depressed or unstable areas were observed. The field inspection observed and noted minor maintenance items to be addressed for the cover system.

Interim Ash Staging Area

The Interim Ash Staging Area is closed and includes a final cap system of soil, with select areas capped with soil and geosynthetics. Final closure design of the Interim Ash Staging Area (AECOM 2016a and 2016c) considered the following general design and operation issues: final cap system installation (including establishment of vegetation cover), drainage and flow management updates, and construction of the Polishing Pond (a portion of which is within the Interim Ash Staging Area footprint).

As part of closure, the Interim Ash Staging Area was generally leveled to conform to the surrounding grades, with gentle slopes (3% maximum) and small perimeter ditches to promote surface drainage. The higher surrounding grade, flat closure grading, and containment toward the east by the Polishing Pond demonstrated in the closure documents promote the overall structural integrity of the CCR containment area.

While this unit is not subject to 40 CFR Part 257.73(d) or (e), closure documents for the Interim Ash Staging Area addressed many aspects of structural integrity listed in the CCR Rule 40 CFR Part 257.73(d) such as settlement, erosion protection, vegetative cover, and structural integrity of underlying hydraulic structures (AECOM 2016a). Prior to closure, TVA performed a geotechnical exploration and analysis to evaluate how final closure of the Interim Ash Staging Area and construction of the Polishing Pond may impact the structural stability of the adjacent dike systems (AECOM 2016a). The scope of work for this assessment is provided below. A summary of the structural evaluations is also provided below. With respect to stability of the waste fill, the assessments considered the following aspects:

- Foundation and abutment conditions (cracking, settlement, deformation, erosion, heave due to seepage): Based on existing analytical data and results, the existing foundations are performing acceptably in comparison to current criteria. As part of the KRP, the area within the Interim Ash Staging Area was prepared as an “Ash Recovery Area” to allow temporary placement of ash while the KRP Ash Landfill was constructed. To prepare the area for the recovered ash processing, prefabricated vertical drains (i.e., PVDs or wick drains) were installed across the Interim Ash Staging Area footprint to expedite consolidation of the existing underlying CCR materials and foundation soils (TVA 2009a, 2009c). Prior to wick drain installation, the footprint was surfaced with a demarcation layer of crushed stone and filter fabric (TVA 2009b) to delineate pre-existing ash (below the stone layer) from temporarily stacked ash from the KRP effort. Prior to closure of the Interim Ash Staging Area and construction of the Polishing Pond, bearing capacity analyses were performed to assess the ability for potential shallow foundations to support the proposed flow management structures (e.g., pipe rack support, junction chamber). Potential consolidation settlement and deformation were also evaluated in the structural support areas. The Polishing Pond was designed and constructed with a liner system consisting of layers of clay, geomembrane, geotextile, and protecting cover such that water within the facility would remain impounded and not affect seepage conditions (AECOM 2016a).

- Slope protection: The Interim Ash Staging Area was generally leveled to conform to the surrounding grades, with gentle slopes (3% maximum) and small perimeter ditches. Site inspection reports generally indicate appropriate maintenance of slope protection features of the

perimeter ditches (TVA 2022), in accordance with the procedures outlined in the *TVA Operations Support Document* (TVA 2011).

- Embankment dike compaction: The Interim Ash Staging Area does not have above grade embankment dikes. The Initial Ash Disposal Area, which was filled in 1967, was located in the footprint of the Interim Ash Staging Area. The Initial Ash Disposal Area was bounded by the North and East Dikes. The North Dike is now below grade, near the boundary of the Interim Ash Staging Area and the KRP Ash Landfill. The East Dike is part of the Sluice Trench and Area East of Sluice Trench. The final soil cover for the Interim Ash Staging Area and the fill materials (CCR material and soil) for the Polishing Pond perimeter berm were subject to compaction requirements (density and moisture) and quality control testing to achieve the specified hydraulic conductivity and/or strength parameters (AECOM 2016d).

- Vegetation of slopes: The Interim Ash Staging Area has a final cap system of soil, with select areas capped with soil and geosynthetics. The closure documents specified the protective cover soil layer to provide protection for geosynthetics, serve as a barrier layer above the geosynthetics, and to support the establishment of vegetation (AECOM 2016d). QA/QC activities included material source verification and inspection during placement and grading. Annual site inspections were conducted and documented regularly following construction of the final cap. The vegetation along the final cap of the Interim Ash Staging Area was found to be adequate, and any deficiencies were identified for repair (TVA 2022).

- Spillway condition and capacity: The Interim Ash Staging Area does not have any spillway features

- Structural integrity of hydraulic structures underlying the base of the CCR unit: As part of the KRP, the area within the Interim Ash Staging Area was prepared as an “Ash Recovery Area.” To prepare the area for the recovered CCR processing, two existing metal cleaning ponds were decommissioned. The clay lined metal cleaning ponds were dewatered, backfilled with layers of shot rock, crushed stone, and compacted fill, and capped with a demarcation layer of crushed stone and filter fabric (TVA 2009b).

TVA further promotes structural integrity of the CCR management units by performing routine inspections. In 2021, an annual inspection of the Interim Ash Staging Area was performed (TVA 2022). The inspection report included a general overview of site conditions and summary of areas of interest. The report also documented a field inspection, which included observations (as applicable) of cover soil, vegetation, drainage ditches, pipes and culverts, pumps, manholes, topography, and access roads. There were no observed deficiencies identified at the Interim Ash Staging Area during inspection that required immediate attention, monitoring, or maintenance.

Sluice Trench and Area East of Sluice Trench

The Sluice Trench and Area East of Sluice Trench is closed and includes a final cap system of soil in some portions and soil plus geosynthetics in other portions. Final closure design of the Sluice Trench and Area East of Sluice Trench was performed as part of three projects: the Drainage and Flow Management

project (AECOM 2016b), the East Dike Seepage Mitigation project (AECOM 2018a), and the East Dike Area Closure project (AECOM 2019). The elements related to closure considered the following general design and operation issues: fill placement, stormwater management system construction, final cap system installation (including establishment of vegetation cover), and access road construction.

In accordance with the CCR Rule, the Sluice Trench and Area East of Sluice Trench was closed and is monitored and maintained in accordance with a *Closure and Post-Closure Plan* (AECOM 2018b). With respect to closure, the plan summarized control of infiltration and releases, prevention of future impoundment of water, sediment, or slurry, slope stability measures, CCR management unit maintenance, drainage and stabilization of surface impoundments, and final cover system design. With respect to post-closure, the plan summarized monitoring and maintenance activities for the final cover system and groundwater monitoring system.

While closure construction was ongoing, TVA performed a structural stability assessment as required by 40 CFR Part 257.73(d) for the KIF Plant Sluice Trench and Area East of Sluice Trench surface impoundment (AECOM 2018c). The scope of work for this assessment is provided below. TVA further promotes structural integrity of the CCR management units by performing routine inspections and by evaluating proper abandonment of hydraulic structures and pipe penetrations through the unit perimeter. A summary of the structural evaluations is also provided below. Additionally, the stability program described in Section 2.2 considers the safety factor aspects of the CCR Rule, 40 CFR Part 257.73(e), such as static and seismic stability.

As part of TVA's ongoing efforts to comply with the CCR Rule, a structural stability assessment was performed for the Sluice Trench and Area East of Sluice Trench (AECOM 2018c). Within this document, "East Dike" refers to the southeast perimeter dike system along the intake channel. The "Non-CCR Process Water Basin" refers to the Polishing Pond that is located partially within the footprint of this CCR management unit. With respect to stability of the waste fill and side slope berms, this assessment considered the following aspects:

- Foundation and abutment conditions (cracking, settlement, deformation, erosion, heave due to seepage): Based on existing analytical data and results, the existing foundations are performing acceptably in comparison to current criteria. Further, no physical or visual evidence of heave or uplift has been observed. Visual inspections of the perimeter road where pipes pass through do not show any signs of deformation. The pipes have been evaluated for buckling stability for two different limit states: usual loading conditions associated with regularly occurring pool levels and unusual loading conditions associated with the design flood event (AECOM 2018c).

- Slope protection: Site inspection reports generally indicate appropriate maintenance of slope protection features of the perimeter dike, in accordance with the procedures outlined in the *TVA Operations Support Document* (TVA 2011)

- Embankment dike compaction: Construction records related to the East Dike (built in the 1950s) were not available. However, TVA design drawing 10N400 provides documentation of placement and compaction requirements related to the construction of the perimeter dike. Later subsurface

explorations confirm that the earth fill used for the East Dike is generally consistent with well compacted fill. Construction criteria related to dike embankment materials and dike compaction as noted on these drawings include:

  - Portions of the dike embankments were placed below water. Fill was placed to the angle of repose
  - Dike embankments were constructed of unclassified excavation
  - For a length of the East Dike closest to the intake, a note on the drawing states “Special care is to be taken to select firm shale material to be placed below the water level, at the location indicated, so that slope will not extend into the area of the intake channel”.

- Spillway condition and capacity: The Sluice Trench and Area East of Sluice Trench does not have any spillway features
- Sudden drawdown assessment (slope stability): The exterior slope of the Non-CCR Process Water Basin was assessed for sudden drawdown (i.e., sudden decrease in the Emory River pool elevation) for slope failures of significant mass, which could directly impact potential release of water and CCR materials from the basin. Based on the assessment of the sudden drawdown for basin, the CCR Rule-related criteria have been met.

In 2020, an annual inspection of the KIF Plant CCR Facilities was performed (TVA 2021). For the Sluice Trench and Area East of Sluice Trench, the inspection report included a general overview of site conditions, summary of areas of interest, and review of instrumentation data. The report also documented a field inspection, which included observations (as applicable) of cover soil, vegetation, drainage ditches, pipes and culverts, pumps, manholes, topography, and access roads. There were no observed deficiencies identified at the Sluice Trench and Area East of Sluice Trench during inspection that required immediate attention, monitoring, or maintenance.

2.3.2 Discussion

For purposes of this section of the EAR, “structural integrity” considers structural potential failure modes that could lead to a release of CCR materials, other than slope stability (addressed in Section 2.1.4) and structural stability of bedrock (addressed in Section 2.4).

For the KIF Plant TDEC Order CCR management units, historical reports were leveraged to address structural integrity. No significant deficiencies were identified with respect to structural integrity of the KIF Plant TDEC Order CCR management units. TVA promotes structural integrity of the units by performing routine inspections and other compliance activities, in accordance with TVA policies, state regulations, and federal regulations.

2.4 STRUCTURAL STABILITY (BEDROCK)

Per the EIP, TDEC requested that TVA discuss the ability of the local geology to provide sufficient structural stability for the existing surface impoundments, landfills, and/or non-registered disposal areas at the KIF Plant as well as any disposal area considered for closure in place.

For purposes of this section of the EAR, "structural stability (bedrock)" considers stability of bedrock below fill areas. That is, the bedrock was evaluated with respect to voids/cavities and faults/joints of significant lateral or vertical extent that could be large enough to lead to loss of structural support and potential release of the overlying CCR materials.

For the KIF Plant TDEC Order CCR management units, the Evaluation of Existing Geotechnical Data (Appendix L of the EIP; Stantec 2018a) summarized historical reports that could be leveraged to address structural stability of the bedrock.

2.4.1 Previous Representative Studies and Assessments

Evaluating the adequacy of existing data depends on the type of data, its quality, and its intended use. For evaluating the stability of bedrock below fill areas, existing data that were considered included:

- Geotechnical data from borings that included rock coring
- Routine visual observations of CCR management units, with respect to indicators of structural distress
- Geologic mapping and characterization of the site, including descriptions of the shallow rock formations.

For this subject, the basis for evaluating the adequacy of each type of data listed above were similar:

- Spatial coverage of borings and visual observations
- Suitability of methods used to perform rock coring and visual observations, and of the associated documentation. Suitability is evaluated qualitatively, based on how well the methods obtained the necessary data and how the methods compared to the current standard of practice.
- Potential for relevant changes in subsurface conditions since borings, surveys, or observations were performed.

General

According to the United States Geological Survey Geologic Map of the Harriman Quadrangle (Moore, Finlayson, and Milici 1993), the plant is underlain by Lower Ordovician and Cambrian age limestone and shale bedrock formations. The majority of the plant, including the Interim Ash Staging Area, Stilling Pond, and Sluice Trench and Area East of Sluice Trench, is underlain by the Conasauga Shale Formation,

which consists of an argillaceous to silty shale with zones of shaley limestone scattered throughout. The geologic mapping indicates this formation is contorted, brecciated, and sheared throughout.

Stilling Pond

In 2009, Stantec performed four borings at the Stilling Pond that included rock coring at depths up to about 20 feet into the bedrock (Stantec 2009). The rock was described as shale interbedded with limestone. The shale was described as gray to dark gray, fine grained, very soft, thin bedded, argillaceous to calcareous with thin limestone partings throughout. The limestone was described as light gray, fine to medium grained, hard, and thin bedded. Core recovery ranged from 0 to 100%, and rock quality designation (RQD) ranged from 0 to 13%. No voids were noted.

In 2010, S&ME performed two borings at the Stilling Pond that included rock coring at depths up to about 20 feet into the bedrock (S&ME 2010). The rock was described as shale interbedded with limestone. The shale was described as dark gray to gray, very fine grained, very soft to soft. The limestone was described as blue-gray, fine to coarse grained, hard, partially crystalline. Core recovery ranged from 0 to 61%, and RQD ranged from 0 to 12%. Intervals were noted to be highly fractured. No voids were noted.

In 2011, S&ME performed 15 borings at the Stilling Pond that included rock coring at depths up to about 10 feet into the bedrock (S&ME 2011). The rock was described as shale interbedded with siltstone and/or limestone. The shale was described as gray to dark gray, fine to medium grained, soft, thin bedded. The siltstone was described as gray to green, hard, and calcareous with white and pink calcite veining. The limestone was described as gray, fine grained, hard. Core recovery ranged from 0 to 100%, and RQD ranged from 0 to 35%. Intervals were noted to be highly fractured. No voids were noted.

In 2014, S&ME performed one boring at the Stilling Pond that included rock coring at a depth of about 25 feet into the bedrock (TVA 2015). The rock was described as siltstone interbedded with limestone, transitioning to siltstone interbedded with shale. The siltstone was described as dark gray to greenish gray, fine grained, soft to medium hard with calcite veining. The limestone was described as gray, hard. The shale was described as dark gray, very fine grained, medium hard. Core recovery ranged from 73 to 100%, and RQD ranged from 0 to 18%. Intervals were noted to be highly fractured. No voids were noted.

Interim Ash Staging Area

In 2011, S&ME performed three borings at the Interim Ash Staging Area that included rock coring at depths up to about 10 feet into the bedrock (S&ME 2011). The rock was described as shale interbedded with siltstone. The shale was described as maroonish gray, very fine grained, very soft, slightly weathered. The siltstone was described as grayish green and gray, soft to moderately hard. Core recovery ranged from 2 to 70%, and RQD was 0%. Intervals were noted to be highly fractured. No voids were noted.

In 2012, AMEC performed two borings at the Interim Ash Staging Area that included rock coring at depths up to about five feet into the bedrock (AMEC 2012). The rock was described as shale with some limestone stringers. The shale was described as gray, soft to moderately hard. Core recovery ranged from 44 to 100%, and RQD ranged from 0 to 35%. No voids were noted.

In 2012, Stantec performed five borings at the Interim Ash Staging Area that included rock coring at depths up to about 14 feet into the bedrock (Stantec 2012a, Stantec 2012b). The rock was described as shale interbedded with siltstone and limestone. The shale was described as dark gray with dull purple gray, soft to moderately hard, thinly bedded. The siltstone is described as light to medium gray, moderately hard, thin to thick bedded. The limestone was described as light gray. Core recovery ranged from 27 to 100%, and RQD ranged from 0 to 14%. Intervals were noted to be highly fractured. No voids were noted.

In 2015, Amec Foster Wheeler performed two borings at the Interim Ash Staging Area that included rock coring at depths up to about 10 feet into the bedrock (Amec Foster Wheeler 2015). The rock was described as shale and some shale interbedded with limestone. The shale was described as very dark greenish gray, very thinly bedded, slightly weathered. The limestone was described as black, to very dark gray, very thinly bedded. Core recovery ranged from 95 to 100%, and RQD ranged from zero to 75%. Intervals were noted to be highly fractured. No voids were noted.

In 2015, URS performed one boring at the Interim Ash Staging Area that included rock coring at depths of about four feet into the bedrock (AECOM 2016a). The rock was described as shale, gray, hard, laminated to thinly bedded, slightly weathered. Core recovery ranged from 22 to 75%, and RQD ranged from 0 to 33%. Intervals were noted to be highly fractured. No voids were noted.

Sluice Trench and Area East of Sluice Trench

In 2010, S&ME performed one boring at the Sluice Trench and Area East of Sluice Trench that included rock coring at a depth of about 20 feet into the bedrock (S&ME 2010). The rock was described as shale with some siltstone. The shale was described as gray to maroon gray and greenish-gray, fine grained, very soft to soft, slightly weathered. The siltstone was described as calcareous. Core recovery ranged from 40 to 76%, and RQD ranged from 0 to 32%. Intervals were noted to be highly fractured. No voids were noted.

In 2011, S&ME performed four borings at the Sluice Trench and Area East of Sluice Trench that included rock coring at depths up to about 17 feet into the bedrock (S&ME 2011). The rock was described as shale, limestone, and shale interbedded with siltstone. The shale was described as dark gray and maroonish gray, very fine grained, soft, slightly weathered. The siltstone was described as gray, moderately hard, slightly weathered. The limestone was described as black and medium gray, fine to medium grained, hard, slightly weathered with large calcite inclusions. Core recovery ranged from 18 to 88%, and RQD ranged from 0 to 8%. No voids were noted.

In 2015, URS performed three borings at the Interim Ash Staging Area that included rock coring at depths up to about nine feet into the bedrock (AECOM 2016a). The rock was described as shale, limestone, and shale interbedded with limestone. The shale was described as light gray to gray, hard, thinly bedded, moderately weathered. The limestone was described as light gray, hard, thinly bedded. Core recovery ranged from 24 to 81%, and RQD ranged from 0 to 58%. No voids were noted.

2.4.2 TDEC Order Environmental Investigation Activities

Per the KIF Plant EXD SAP and Hydrogeological Investigation (HGI) SAP, no rock coring was required to achieve the SAP objectives.

2.4.3 Results

Stilling Pond

No rock coring was performed at the Stilling Pond during the EXD or HGI field activities.

Interim Ash Staging Area

No rock coring was performed at the Interim Ash Staging Area during the EXD or HGI field activities.

Sluice Trench and Area East of Sluice Trench

No rock coring was performed at the Sluice Trench and Area East of Sluice Trench during the EXD or HGI field activities.

2.4.4 Discussion

For purposes of this section of the EAR, “structural stability (bedrock)” considers stability of bedrock below fill areas. That is, the bedrock was evaluated with respect to voids/cavities and faults/joints of significant lateral or vertical extent that could be large enough to lead to loss of structural support and potential release of the overlying CCR materials.

The KIF Plant TDEC Order CCR management units are underlain by the Conasauga Shale formation. Locally, the Conasauga formation shows little variation in composition and condition and is primarily shale interbedded with limestone and siltstone. Based upon the site-specific geologic mapping, rock core borings, and CCR management unit operational performance, there is no evidence of large voids/cavities that could lead to loss of structural support and potential release of the overlying CCR materials.

3.0 CCR MATERIAL CHARACTERISTICS

The objective of the CCR material characterization was to assess the presence of constituents in and their susceptibility to leach from CCR material. The CCR materials at the KIF Plant were evaluated during the EI as well as during an earlier investigation that occurred while the Stilling Pond closure activities were underway and before the EIP was finalized. The activities associated with the two programs are described separately below.

Environmental Investigation

Borings were advanced into two KIF Plant TDEC Order CCR management units (the Sluice Trench and Area East of Sluice Trench and Interim Ash Staging Area) for the collection and analysis of CCR solid matrix samples for total metals and synthetic precipitation leaching procedure (SPLP) metals, installation of temporary wells, and collection of pore water samples. Pore water is subsurface water that occurs in pore spaces in CCR material. TVA visually characterized the CCR material present at each of the boring locations using the Unified Soil Classification System, which classifies material by grain size distribution followed by the material's textural properties. Additional CCR material characterization completed during the investigation included hydraulic conductivity testing of the CCR material at the screened interval of five temporary wells. Exhibit G.1-5 shows the boring and temporary well locations.

TVA performed investigation sample and data collection activities in accordance with the EIP, *CCR Material Characteristics SAP* (Stantec 2018e), *QAPP* and TVA's Environmental Technical Instructions. Sample location selection, collection methodology, analyses, and Quality Assurance/Quality Control (QA/QC) completed for the investigation are provided in the *CCR Material Characteristics Investigation SAR* included in Appendix G.5.

As reported in the *CCR Material Characteristics Investigation SAR*, the data collected during these investigations were deemed usable for reporting and evaluation in this EAR because they met the objectives of the *EIP*.

The scope of work of the CCR material characteristics investigation consisted of the following tasks:

- Collecting CCR material samples and associated QC samples at multiple depths from the boring locations for laboratory analysis of CCR-related constituents listed in Appendices III and IV of the CCR Rule. In addition, five inorganic constituents listed in Appendix I of Tennessee Rule 0400-11-01-.04 and not included in the 40 CFR 257 Appendices III and IV were analyzed to maintain continuity with the TDEC compliance programs. These additional TDEC Appendix I constituents included copper, nickel, silver, vanadium, and zinc. The combined federal CCR Appendices III and IV constituents and TDEC Appendix I inorganic constituents are hereafter referred to as CCR Parameters. In addition, total organic carbon (TOC), iron, and manganese were added as specific parameters of interest to be analyzed per the *CCR Material Characteristics SAP*. SPLP analyses were performed for metals and radiological parameters.

- Identifying the interface between CCR material and underlying foundation soils
- Recording field measurements of CCR material pH
- Collecting pore water level measurements
- Collecting pore water samples and associated QC samples from the temporary wells for analysis of CCR Parameters, TOC, iron, manganese, and field water quality parameters per the *CCR Material Characteristics SAP*.

The boring and temporary well locations are shown on Exhibit G.1-5.

Temporary monitoring wells were installed and completed above the foundation soils at five locations. Following installation of the temporary wells, seven additional borings (KIF-B01a, KIF-B01b, KIF-B02a, KIF-B02b, KIF-B03a, KIF-B03b, and KIF-B04a) were advanced and sampled to fulfill the scope for both the exploratory drilling and CCR material characteristics investigations. Following well installation and development, the horizontal hydraulic conductivity of the CCR material interval intersected by the well screen was estimated by conducting slug tests. The calculated hydraulic conductivities of the CCR material ranged from 9.61×10^{-4} centimeters per second (cm/sec) at KIF-TW01 to 1.43×10^{-2} cm/sec at KIF-TW04. Temporary well construction details and hydraulic conductivity testing data are included in the *Exploratory Drilling SAR* (Appendix G.2).

Tabulated laboratory analytical data for the CCR material and SPLP samples are provided in the *CCR Material Characteristics Investigation SAR* (Appendix G.5) and Table G.1-3 for pore water.

2017 Stilling Pond Investigation

Pore water and CCR material were collected from the Stilling Pond in November 2017 while the Stilling Pond closure activities were underway and before the EIP was finalized in 2018. One pore water sample was collected from each of the three temporary wells shown in Exhibit G.1-5 and analyzed for CCR Parameters (except chloride, fluoride, and sulfate due to a laboratory error), TOC, iron and manganese. CCR material samples were collected from each of the borings and analyzed for CCR Parameters, TOC, iron, and manganese. The CCR material samples were additionally subjected to SPLP testing, similar to the samples collected under the EI. Pore water results from the Stilling Pond investigation are summarized in Table G.1-3, and the CCR material solids and SPLP data are summarized in Table G.1-4.

3.1.1 Physical Properties

Encountered CCR material predominantly consisted of silt to sand to gravel-sized materials. Minor gradational changes, such as silty sand grading to sandy silt, were common throughout the vertical profile of each CCR management unit. The CCR material in each of the units typically was gray in color, but black, blue, brown, yellow, red, and green shades were also described.

Lithologic descriptions of the encountered CCR material are provided in the temporary well boring logs provided in Appendix B.3.

3.1.2 Pore Water Field Parameters

TVA measured field water quality parameters, including pH, specific conductance, dissolved oxygen (DO), temperature, oxidation reduction potential (ORP), and turbidity during the collection of pore water samples at each temporary well. Measured pore water field parameter results are summarized in Table B.7 of the *CCR Material Characteristics Investigation SAR* (Appendix G.5) and Table G.1-3.

An evaluation of the field parameters showed that the general pore water quality conditions within the various CCR management units were similar, including the Stilling Pond data from the 2017 Stilling Pond Investigation. Pore water pH ranged from neutral to alkaline, ranging from 6.53 to 8.86. DO concentrations ranged from 0.36 milligrams per liter (mg/L) to 6.84 mg/L, and ORP results suggested that pore water was under reducing conditions based on negative ORP measurements, ranging from –168.4 to -33.0 millivolts. Measured pore water specific conductance values, which correlate with total dissolved solids (TDS) concentrations, were generally similar or higher in the Interim Ash Staging Area (1,119 microsiemens per centimeter [µS/cm] to 2,832 µS/cm) than in the Sluice Trench and Area East of Sluice Trench (892 µS/cm to 1,979 µS/cm). Conductivity[2] measured in the Stilling Pond was low in comparison and ranged from 0.447 µS/cm to 1.264 µS/cm. Measured pore water turbidities for the Sluice Trench and Area East of Sluice Trench and Interim Ash Staging Area were between 3.2 nephelometric turbidity units (NTUs) and 36.1 NTUs.

The maximum turbidity measured was 616.3 NTUs from GP-17-102. This result was higher than other turbidity measurements collected in the Stilling Pond, the Sluice Trench and Area East of Sluice Trench, and the Interim Ash Staging Area. Using statistical evaluation methods described in Appendix E.2, the turbidity measurement collected from GP-17-102 was determined to be a statistical outlier. Because of the high turbidity result and the affect that turbidity can have on analytical results for CCR constituents, analytical results for the pore water sample collected from GP-17-102 were excluded from further statistical analysis.

3.1.3 Analytical Results

TDEC requested that total metals and SPLP analyses be conducted to evaluate CCR material leaching potential. A summary of the findings from the CCR material analytical results is provided in the following subsections.

CCR Material Total Metals and SPLP Analyses

TVA collected and analyzed approximately 54 CCR material grab samples from discrete depth intervals at 12 boring locations from the surface to the base of the Interim Ash Staging Area and Sluice Trench and Area East of Sluice Trench. The resultant analytical dataset represents a vertical profile of total and SPLP concentrations at each boring location. Laboratory analytical data for the CCR material samples are

[2] Conductivity and specific conductance are functionally equivalent measurements; however, specific conductance takes into account the temperature of the sample and conductivity does not. This difference can result in slight variations in the reported values between the two methods.

tabulated in the *CCR Material Characteristics Investigation SAR* (Appendix G.5). Three additional CCR material grab samples were collected from the three borings installed in the Stilling Pond.

Descriptive statistics of the CCR material analytical results were developed and are provided in Appendix E.2. The statistical summaries are provided for each by CCR Parameter and for each CCR management unit. A graphical comparison of the representative concentration ranges at each boring are presented as side-by-side concentration box plots.

A similar descriptive statistics summary of the SPLP results for each CCR material sample is provided in Appendix E.2. For each CCR material sample, statistical analyses were conducted on data where CCR Parameters were detected in greater than 50 percent (%) of the samples in both the SPLP and CCR material datasets. The purpose of the analysis was to evaluate whether the total concentrations of metals in CCR material could be used as a reliable predictor of potential leachable concentrations as represented by SPLP results. Scatter plots with best fit regression lines and Pearson's correlation coefficients were constructed to compare SPLP to total metal concentrations.

The statistical relationships between SPLP concentrations and CCR material concentrations were inconsistent and highly variable. One would expect SPLP concentrations to increase with increasing CCR constituent concentrations in CCR material (i.e., exhibit a regression line with a positive slope). However, this relationship was inconsistent between different CCR constituents and between KIF Plant TDEC Order CCR management units. In some cases, even when there was a statistically significant correlation (e.g., boron), the correlation was inconsistent between the different CCR management units.

For the Stilling Pond, there was insufficient data to evaluate the relationship between concentrations of CCR material and SPLP results.

Pore Water/SPLP Comparison

In November 2017, one pore water sample was collected from each temporary well installed in the Stilling Pond for CCR Parameters (with the exception of chloride, fluoride, and sulfate), iron, manganese, and TOC analysis following well installation and development, to complete the scope of the EI. In addition, these samples were analyzed for aluminum, magnesium, potassium, sodium, strontium, TSS, and speciated arsenic. In April 2019, one pore water sample was collected at each of the five temporary wells installed in the Interim Ash Staging Area and the Sluice Trench and Area East of Sluice Trench for CCR Parameters, iron, manganese, and TOC analysis following well installation and development, to complete the scope of the EI. Samples were collected for analysis of dissolved and total metals. The samples collected for dissolved metals were filtered to remove suspended solids prior to laboratory analysis. The samples collected for total metals were not filtered prior to laboratory analysis. Comparison of the reported concentrations of dissolved and total metals provides an indication of the effect that suspended solids included in the sample may have had on the reported concentrations for total metals analyses. Pore water analytical data are tabulated in Table G.1-3. Descriptive statistics of the pore water analytical results were developed and are provided in Appendix E.2. Two other pore water sampling events were conducted as part of other investigations. The analytical results of those sampling events are included in the discussion of pore water quality below.

TVA compared pore water analytical results to SPLP results for the CCR material to evaluate whether the SPLP methodology could be used to predict pore water concentrations (see Appendix E.2) for CCR constituents. In general, the CCR constituent concentrations using SPLP methodology underestimated CCR constituent concentrations observed in pore water. For CCR Rule Appendix IV CCR constituents (some of which are also TDEC Appendix I constituents) that have been detected in groundwater samples at concentrations above groundwater screening levels (GSLs), the general findings were:

- The range of cobalt concentrations for SPLP results was greater than the range for pore water. The mean concentration for SPLP results was greater than the mean for pore water for the Sluice Trench and Area East of Sluice Trench, but the mean concentrations were similar for the Interim Ash Storage Area.

The results indicate that direct measurement of pore water concentrations is the most accurate way of characterizing potential leachability of CCR constituents from CCR material, but geochemical modeling is needed to predict the concentrations of constituents in groundwater.

In addition to total metals concentrations for pore water, descriptive statistics were also produced for dissolved metals concentrations for pore water (see Appendix E.2). The detected minimum and maximum concentrations, and mean concentrations were similar for cobalt. The results indicated that the amount of turbidity above 5 NTUs only had a small effect on the pore water analytical results, except for the sample collected from GP-17-102 which is considered an outlier because of the high turbidity.

3.1.4 Phreatic Surface Levels

TVA measured pore water levels within the temporary wells monthly for six months. In addition, the wells were gauged during bi-monthly groundwater sampling events. This information was combined with available information from other instruments to develop maps of the phreatic surfaces for each CCR management unit at the time of gauging. The phreatic surface is the surface of pore water at which pressure is atmospheric and below which CCR material may be saturated with pore water. The use of the term “saturated” or references to the moisture content of CCR material does not imply that the pore water is readily separable from the CCR material. Saturated CCR material can have a range of moisture contents based on the characteristics of the material. Pore water levels were not available for the temporary wells installed in the Stilling Pond due to the wells being abandoned for cap system placement over the Stilling Pond CCR management unit. Pore water levels were available from piezometers installed in the Stilling Pond; however, the dataset was not of sufficient density for pore water elevation contours to be drawn for this CCR management unit. Exhibit G.1-6 provides a representative phreatic surface elevation contour map for Event #3 conducted in August 2019 for the Interim Ash Staging Area and Sluice Trench and Area East of Sluice Trench. Table G.1-5 provides a summary of the pore water gauging data for the August 2019 sampling event. The data for other gauging events can be found in Table 4.1 of the EAR and Appendices H.3, H.4, H.6, H.7, and H.8.

Each of the TDEC Order CCR management units was previously closed in accordance with applicable regulations in effect at the time of closure. The pore water levels reported herein may not represent steady-state conditions.

3.1.5 Pore Water Quality Evaluation

This section provides a discussion of the analytical results for pore water samples collected from temporary wells installed as part of the EI. Pore water samples were collected from the temporary wells during four sampling events. The second sampling event was conducted as part of the EI. The first, third, and fourth sampling events were conducted as part of activities associated with other investigations at the KIF Plant.

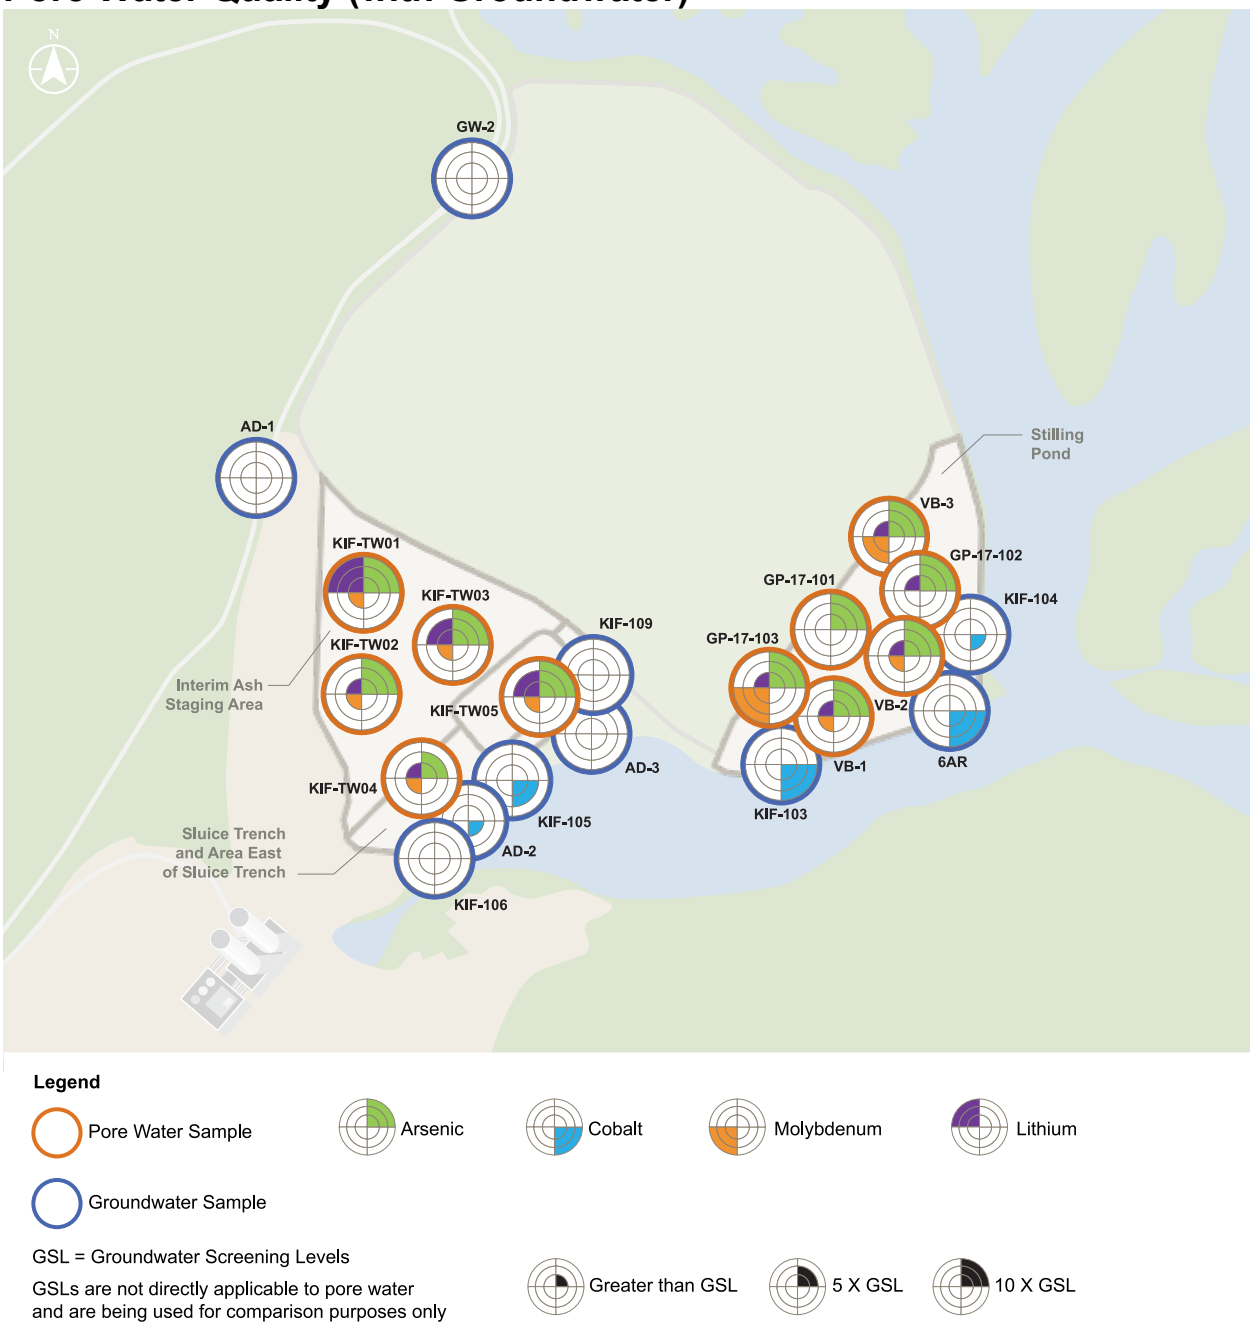
Table G.1-3 provides a summary of pore water analytical results from the following sampling events.

- November 2017 (GP-17-101, GP-17-102, GP-17-103)
- April 2019 (KIF-TW01, KIF-TW02, KIF-TW03, KIF-TW04, KIF-TW05)
- March 2021 (KIF-TW01, KIF-TW02, KIF-TW03, KIF-TW04, KIF-TW05, VB-1, VB-2, VB-3)
- April 2021 (KIF-TW01, KIF-TW02, KIF-TW03, KIF-TW04, KIF-TW05, VB-1, VB-2, VB-3)

The pore water characterization evaluation is based on a comparison of pore water concentrations to groundwater concentrations and GSLs across the KIF Plant. GSLs are not directly applicable to pore water. Comparing pore water concentrations to GSLs is used to identify CCR constituents that have some potential to impact groundwater downgradient of CCR management units. Pore water concentrations were compared to GSLs for constituents listed in Appendix I of TDEC Rule 0400-11-01-.04 (TDEC Appendix I) and in Appendix IV of the CCR Rule because these constituents are subject to potential corrective measures.

Three TDEC Appendix I or CCR Rule Appendix IV constituents (arsenic, lithium, and molybdenum) had reported concentrations in one or more pore water samples above a GSL. None of these, constituents had statistically significant concentrations in groundwater above a GSL. Cobalt is the only constituent with a statistically significant concentration in groundwater above a GSL. The figure below summarizes reported pore water and groundwater analytical results and their comparisons to GSLs. The locations of temporary pore water wells are shown as symbols with an orange outer ring; groundwater well symbols have a blue outer ring. The colored slices in each symbol indicate CCR constituents detected above a GSL in each temporary pore water well. The number of colored sections within each slice represents the magnitude of the reported concentrations relative to the GSL. The legend provides further explanation of the colors and rings.

Pore Water Quality (with Groundwater)



There is a distinct difference between pore water and groundwater quality. As these figures illustrate, many constituents detected above a GSL in pore water samples were below the applicable GSLs in groundwater samples from the same areas.

For the one constituent detected in groundwater above a GSL, the sample had turbidity of 616.3 NTUs. The generally high concentrations of CCR constituents reported in this sample are interpreted to be a result of the high turbidity.

In addition, Attachment G.1-A provides graphs that show the results of the pore water samples over time for constituent-well pairs with one or more reported concentrations above a GSL. Analytical results for total and dissolved fractions of samples are plotted adjacent to one another for each sampling event. The difference between total and dissolved metals results provides an indication of whether suspended solids materially affect the reported concentrations in the total metals analyses. In addition, the GSL was added to the graphs to illustrate the differences between pore water and the GSL. Observations about the graphs follow:

- Except for the April samples collected from KIF-TW05, concentrations generally showed little variation over time as demonstrated by the predominantly horizontal graphs.
- Certain constituents in the samples collected from KIF-TW05, for example arsenic and molybdenum, had lower reported results for the last sampling event.
- The difference between the concentrations of total and dissolved constituents for samples collected from GP-17-102 (including the detection of additional constituents not shown in the graphs) is interpreted to be due to the high turbidity readings during sample collection. The sample had turbidity readings of 616 NTUs. This turbidity reading indicates a potential for suspended solids to affect analytical results for the sample.
- Constituents detected in pore water samples above a GSL were not detected in groundwater samples at statistically significant concentrations above a GSL.

In summary, there is a distinct difference between pore water and groundwater quality. Three CCR Rule Appendix IV or TDEC Appendix I constituents had reported concentrations in pore water above a GSL. None of these constituents had statistically significant concentrations in groundwater above a GSL. Generally, pore water concentrations were stable over the sampling period, and suspended solids did not materially affect reported concentrations for total metal analyses.

3.1.6 Summary

The objective of the CCR material characterization was to assess both the presence of CCR constituents within CCR material and their potential to leach from CCR material. TVA evaluated the usefulness of total metals and SPLP analyses as a predictor of CCR constituent concentrations in pore water. In addition, TVA compared the SPLP analytical results to the pore water sample results. The evaluations found that total concentrations of metals in CCR material are not a reliable predictor of the magnitude of the potentially leached concentrations using SPLP, and SPLP analysis of CCR material does not reliably predict pore water concentrations. The results indicated that direct measurement of pore water concentrations is the most accurate way of characterizing potential leachability of CCR constituents from CCR material, but geochemical modeling is needed to predict the concentrations of constituents in groundwater.

APPENDIX G.1 – TECHNICAL EVALUATION OF GEOTECHNICAL AND CCR MATERIAL CHARACTERISTICS DATA

CCR Material Characteristics
March 12, 2024

TVA evaluated analytical results for pore water based on data collected under the EI and for other investigations. In summary, there is a distinct difference between pore water and groundwater quality. Three CCR Rule Appendix IV or TDEC Appendix I constituents had reported concentrations in pore water above a GSL. None of these constituents had statistically significant concentrations in groundwater above a GSL. Generally, pore water concentrations were stable over the sampling period, and suspended solids did not materially affect reported concentrations for total metal analyses.

PZ-B1*	19-Aug-19	14.2	766.69	752.5	759.3	734.1	25.2	n/a	CCR Material

Notes:

*	Piezometer is manually gauged. Groundwater elevation is calculated to nearest 0.01 from surveyed top of casing
bgs	below ground surface
btoc	below top of casing
CCR	coal combustion residuals
ft	feet
ID	identification
msl	mean sea level
n/a	not applicable
NM	not measured

1. Top of casing elevations, screen intervals, and screened formations were obtained from boring logs, well detail and well survey data.
2. For piezometers, ground surface elevation, pore water elevations, and piezometer data obtained from geotechnical instrumentation database. Vibrating wire sensor formation information were obtained from boring logs. Data from automated piezometers are averaged for the measurement date.
3. Pore water elevations in piezometers are calculated values. Accuracy of piezometer data is to 0.1 ft.
4. Screen interval shown for temporary wells is below ground surface when drilled.
5. In select piezometers noted as "NM" above, pore water elevation data were not available for this event.

- Polishing Pond (Approximate)

Notes

1. Coordinate System: NAD 1983 StatePlane Tennessee FIPS 4100 Feet
2. Imagery provided by Esri World Imagery from February 2020
3. During the construction of the Perimeter Containment Soil-Cement Stabilization, top of rock elevations were determined by a combination of predrilling (S&ME 2011) and trench excavations. This top of rock information is available for the entirety of the Stabilization alignment and the spacing between top of rock observations range from approximately 15 feet to 20 feet.

1.0 INTRODUCTION

Stantec Consulting Services Inc. (Stantec) has prepared this sampling and analysis report (SAR), on behalf of the Tennessee Valley Authority (TVA), to document activities related to exploratory drilling (EXD) at TVA's Kingston Fossil (KIF) Plant located in Roane County, Tennessee.

The purpose of the EXD was to drill borings, install temporary wells, and install piezometers to evaluate subsurface conditions at the KIF Plant, in support of fulfilling the requirements for the Tennessee Department of Environment and Conservation (TDEC) issued Commissioner's Order No. OGC15-0177 (TDEC Order) to TVA (TDEC 2015). The TDEC Order sets forth a "process for the investigation, assessment, and remediation of unacceptable risks" at TVA's coal ash disposal sites in Tennessee.

The purpose of this SAR is to summarize activities completed to meet the objectives of the EXD Sampling and Analysis Plan (SAP) (Stantec 2018a) and the Addendum to Exploratory Drilling SAP (EXD SAP Addendum) (Stantec 2020). This SAR is not intended to provide conclusions or evaluations of results. The scope of the EXD activities represented herein was conducted pursuant to the EXD SAP and SAP Addendum and is part of a larger environmental investigation at the KIF Plant. The evaluation of the results will consider other aspects of the environmental investigation at the KIF Plant, including data collected under other State and/or coal combustion residuals (CCR) programs and will be presented in the Environmental Assessment Report (EAR).

The EXD activities were performed in conjunction with CCR materials characterization and material quantity investigations in general accordance with the following documents developed by TVA to support fulfilling the requirements of the TDEC Order:

- *Exploratory Drilling SAP* (Stantec 2018a)
- *Addendum to Exploratory Drilling SAP* (Stantec 2020)
- *Environmental Investigation Plan* (Stantec 2018b)
- *CCR Material Characteristics SAP* (Stantec 2018c)
- *Material Quantity SAP* (Stantec 2018d)
- *Groundwater Investigation SAP* (Stantec 2018e)
- *Quality Assurance Project Plan (QAPP)* (Environmental Standards, Inc. 2018).

The exploratory drilling was implemented in accordance with TVA and TDEC-approved Programmatic- and Project-specific changes. Minor variations in scope and procedures from those outlined in the KIF Plant EXD SAP and SAP Addendum occurred during field activities due to field conditions and programmatic updates and are referenced in Section 3.11.

EXD field work was conducted in two phases (Phase 1 and Phase 2) and consisted of three primary activities – drilling and sampling, installing temporary wells, and installing piezometers. Quality Assurance oversight of field data acquisition protocols, sampling practices, and field data review were performed by Environmental Standards, Inc. (EnvStds) under direct contract to TVA. Geotechnical laboratory testing and data review was performed by Stantec.

2.0 OBJECTIVE AND SCOPE

2.1 PHASE 1 EXPLORATORY DRILLING

The primary objective of the Phase 1 EXD, conducted pursuant to the EXD SAP, was to perform borings and install temporary wells to further characterize subsurface conditions at the KIF Plant, in response to the TDEC Order. The EXD SAP included activities at two CCR units: the Interim Ash Staging Area and the Sluice Trench and Ballfield East of Sluice Trench.

The activities conducted during Phase 1 EXD support data collection for the CCR material characteristics and material quantity investigations at the KIF Plant, including pore water level measurements and soil sample collection for analysis of CCR-related constituents.

The approach for Phase 1 EXD was to:

- Perform soil borings and geotechnical laboratory testing to refine subsurface characterization and material quantity estimates
- Install temporary wells to allow for pore water sampling and measuring piezometric (i.e., pore water) levels within CCR units
- Use either hollow-stem auger or direct-push technology (DPT) drilling techniques to collect soil samples at staked boring locations approved by TDEC and considered suitable for the drill rig to safely access
- Complete temporary well development, hydraulic conductivity (slug) testing, and survey activities.

The scope of work of the Phase 1 EXD consisted of the following tasks:

- Drilling borings
- Collecting disturbed and undisturbed soil samples for lithologic information
- Installing temporary wells, constructing surface protections, and developing the wells
- Conducting slug tests in temporary wells
- Performing geotechnical laboratory testing
- Surveying boring and temporary well locations.

Details on each Phase 1 EXD activity are presented in the sections below. These activities were carried out concurrently with CCR material sampling and pore water monitoring and sampling, which were performed in accordance with the CCR Material Characteristics and Material Quantity SAPs. Refer to the CCR Material Characterization and Material Quantity SARs for information from those concurrent activities.

2.2 PHASE 2 EXPLORATORY DRILLING

The primary objective of the Phase 2 EXD, conducted pursuant to the EXD SAP Addendum, was to perform borings and install piezometers to further characterize subsurface conditions at the KIF Plant, in response to the TDEC Order. The EXD SAP Addendum included activities at one CCR unit: the Sluice Trench and Ballfield East of Sluice Trench.

The approach for the Phase 2 EXD was to:

- Perform a bathymetric survey within the Intake Channel adjacent to the East Dike
- Perform soil borings and geotechnical laboratory testing to refine subsurface characterization
- Install vibrating wire piezometers (VWPs) to allow water level (i.e., pore water pressure) readings in various materials
- Use mud rotary techniques to collect soil samples at staked boring locations approved by TDEC and considered suitable for the drill rig to safely access.

The scope of work of the Phase 2 EXD consisted of the following tasks:

- Drilling borings
- Collecting disturbed and undisturbed soil samples for lithologic information
- Installing VWPs
- Performing geotechnical laboratory testing
- Surveying boring locations.

Details on each Phase 2 EXD activity are presented in the sections below.

3.0 FIELD ACTIVITIES

Stantec performed Phase 1 and Phase 2 EXD field activities based on guidance and specifications listed in TVA's Environmental (ENV) Technical Instructions (TIs), the SAPs, and the QAPP, except as noted in the Variations section of this report. As part of TVA's commitment to generate representative and reliable data, oversight of select field activities, field documentation and centralized data management were performed by EnvStds under direct contract with TVA. EnvStds also conducted audits of field activities and provided quality reviews of field documentation.

3.1 PHASE 1 ACTIVITIES

EXD field activities were conducted in several separate intervals. The first two intervals were conducted between November 12 and 15, 2018 and January 22 and February 28, 2019, and consisted of hollow-stem auger drilling and temporary well installation. Temporary well development was conducted between April 2 and 8, 2019. Temporary well slug testing was conducted between June 18 and 20, 2019. Supplemental drilling was conducted between December 2 and 6, 2019, and consisted of DPT drilling. Prior to initiating field activities, TVA conducted environmental reviews, obtained permits, and performed utility clearances as necessary to complete the field work.

During the Phase 1 EXD, Stantec conducted the following field activities:

- Confirmed drilling locations for planned boring locations
- Drilled an initial seven borings within the Interim Ash Staging Area and the Sluice Trench and Ballfield East of Sluice Trench, under the direction of a Stantec Professional Geologist (PG) licensed in the State of Tennessee
- Collected soil samples to develop a continuous subsurface log/soil profile for each boring, with select soil samples subjected to geotechnical laboratory testing
- Installed temporary wells in five of the borings, under the direction of a Stantec PG licensed in the State of Tennessee
- Developed each temporary well and conducted slug tests to estimate hydraulic conductivity
- Drilled seven supplemental borings, for additional sampling needs, adjacent to select temporary well locations.

Following temporary well installation and supplemental drilling, temporary well surface protections were constructed, and each boring location was surveyed.

Appendix A provides a site location map and a Phase 1 EXD boring (and temporary well) location map. Appendix B provides summary tables of information collected during the Phase 1 EXD. Appendix C includes subsurface logs and temporary well installation details. Appendix D includes photographs related

to the borings and temporary wells. Appendix E includes in-situ testing results and Appendix F includes geotechnical laboratory testing results.

3.2 PHASE 2 ACTIVITIES

TVA performed the bathymetric survey within the Intake Channel on December 3, 2020. Phase 2 EXD field activities were conducted by Stantec between January 25 and February 26, 2021 and consisted of geotechnical borings. Prior to initiating field activities, TVA conducted environmental reviews, obtained permits, and performed utility clearances as necessary to complete the field work.

During the Phase 2 EXD, Stantec conducted the following field activities:

- Confirmed drilling locations for planned boring locations
- Drilled 12 borings within the Sluice Trench and Ballfield East of Sluice Trench, under the direction of a Stantec Professional Engineer (PE) licensed in the State of Tennessee
- Collected soil samples to develop a subsurface log/soil profile for each boring, with select soil samples subjected to geotechnical laboratory testing
- Installed six VWPs in three geotechnical borings

Following completion of the Phase 2 borings, each boring location was surveyed.

Appendix A provides a Phase 2 EXD boring location map and an instrument location map. Appendix B provides summary tables of information collected during the Phase 2 EXD. Appendix C includes subsurface logs and instrument installation details. Appendix D includes photographs related to the borings and instruments. Appendix E includes in-situ testing results and Appendix F includes geotechnical laboratory testing results. Appendix G includes a contour map for the top of sediment/soil within the limits of the bathymetric survey.

3.3 WORK LOCATIONS

3.3.1 Phase 1 Work Locations

The Phase 1 boring locations were selected to address data gaps and supplement existing data at the KIF Plant as described in the EXD SAP. Rationale for individual boring locations is discussed below. A site location map and boring locations map are provided as Exhibits A.1 and A.2, respectively, in Appendix A.

In order to provide data regarding CCR material quantity, pore water levels, CCR material characteristics, and subsurface characterization, borings were drilled, and temporary wells installed at locations shown on Exhibit A.2. A total of 14 borings, five of which include temporary well installations, were completed. Table 1 provides the number of borings completed (including temporary well installations) in each CCR unit. Table 2 lists the borings and more detail about the purpose for each.

Table 1. Phase 1 Exploratory Drilling Performed in Each CCR Unit

CCR Unit	No. of Borings without Temporary Wells	No. of Borings with Temporary Wells Installed
Interim Ash Staging Area	8	3
Sluice Trench and Ballfield East of Sluice Trench	1	2
Total	**9**	**5**

Table 2. Summary of Phase 1 EXD Borings

Boring No.	CCR Unit	Borehole Termination Criteria	Temporary Well Screen Location	Boring Purpose
KIF-TW01	Interim Ash Staging Area	Sample Uppermost Foundation Soil	Sluiced Ash	PZ, PW, Geo
KIF-TW02	Interim Ash Staging Area	Sample Uppermost Foundation Soil	Sluiced Ash	PZ, PW, Geo
KIF-TW03a	Interim Ash Staging Area	Sample Uppermost Foundation Soil	Not Installed	Geo
KIF-TW03b	Interim Ash Staging Area	Sample Uppermost Foundation Soil	Not Installed	Geo
KIF-TW03	Interim Ash Staging Area	Sample Uppermost Foundation Soil	Sluiced Ash	PZ, PW, Geo
KIF-TW04	Sluice Trench and Ballfield East of Sluice Trench	Sample Uppermost Foundation Soil	Sluiced Ash	PZ, PW, Geo
KIF-TW05	Sluice Trench and Ballfield East of Sluice Trench	Sample Uppermost Foundation Soil	Sluiced Ash	PZ, PW, Geo

KIF-B01b	Interim Ash Staging Area	Sample Uppermost Foundation Soil	N/A	Geo
KIF-B02a	Interim Ash Staging Area	Sample Uppermost Foundation Soil	N/A	Geo
KIF-B02b	Interim Ash Staging Area	Sample Uppermost Foundation Soil	N/A	Geo
KIF-B03a	Interim Ash Staging Area	Sample Uppermost Foundation Soil	N/A	Geo
KIF-B03b	Interim Ash Staging Area	Sample Uppermost Foundation Soil	N/A	Geo
KIF-B04a	Sluice Trench and Ballfield East of Sluice Trench	Sample Uppermost Foundation Soil	N/A	Geo

Notes:
PZ = Piezometric (Pore Water) Levels in CCR;
PW = Pore Water Sampling;
Geo = Geotechnical Data
N/A = Not Applicable
KIF-TW03a and KIF-TW03b encountered obstructions prior to reaching the planned termination depth. Borings did not reach the uppermost foundation soil. See Section 3.10.

As shown on Exhibit A.2 in Appendix A, a total of 14 borings, including five borings with temporary wells (labeled KIF-TW01 through KIF-TW05), were drilled within the footprints of the Interim Ash Staging Area (three temporary wells) and Sluice Trench and Ballfield East of Sluice Trench (two temporary wells). The

borings are located in accessible areas of the unit interiors to improve spatial coverage for CCR material thickness and pore water levels, and to facilitate CCR material characterization and pore water sampling. The temporary wells were screened near the bottom of the CCR in the units, after the portion of the borehole was sealed that penetrated the foundation soils.

The supplemental borings were located within a 25-foot radius of the associated temporary well (e.g., KIF-B01a and KIF-B01b were associated with KIF-TW01). Typically, two supplemental borings were performed at each proposed location within approximately five feet of each other. Pairs of borings were typically necessary to generate adequate sample volume for various laboratory testing needs. However, only one supplemental boring (KIF-B04a) was necessary adjacent to temporary well KIF-TW04. No supplemental borings were necessary adjacent to temporary well KIF-TW05.

3.3.2 Phase 2 Work Locations

The Phase 2 boring locations were selected to address data gaps and supplement existing data at the KIF Plant as described in the EXD SAP Addendum. Rationale for individual boring locations is discussed below. A Phase 2 boring location map and an instrument location map are provided as Exhibits A.3 and A.4, respectively, in Appendix A.

In order to provide data regarding pore water levels, CCR material characteristics, and subsurface characterization, borings were drilled and VWPs installed at locations shown on Exhibits A.3 and A.4. A total of 12 borings were completed. Table 3 provides the number of borings completed (including VWP installations) in each CCR unit. Table 4 lists the borings and more detail about the purpose for each.

Table 3. Phase 2 Exploratory Drilling Performed in Each CCR Unit

CCR Unit	No. of Borings without VWPs	No. of Borings with VWPs Installed
Sluice Trench and Ballfield East of Sluice Trench	9	3
Total	**9**	**3**

Notes:
CCR = Coal Combustion Residuals
VWP = Vibrating Wire Piezometer

Table 4. Summary of Phase 2 EXD Borings

Boring No.	CCR Unit	Borehole Termination Criteria	VWP Tip Location(s)	Boring Purpose
KIF-B05	Sluice Trench and Ballfield East of Sluice Trench	Refusal	Foundation Soils	PZ, Geo
KIF-B06	Sluice Trench and Ballfield East of Sluice Trench	Refusal[1]	--	Geo
KIF-B07	Sluice Trench and Ballfield East of Sluice Trench	Refusal[1]	--	Geo
KIF-B08	Sluice Trench and Ballfield East of Sluice Trench	Refusal	--	Geo
KIF-B09	Sluice Trench and Ballfield East of Sluice Trench	Refusal	Foundation Soils	PZ, Geo

KIF-B12	Sluice Trench and Ballfield East of Sluice Trench	Refusal[1]	--	Geo
KIF-B13	Sluice Trench and Ballfield East of Sluice Trench	Refusal[1]	Foundation Soils	Geo, PZ
KIF-B14	Sluice Trench and Ballfield East of Sluice Trench	Refusal	--	Geo
KIF-B15	Sluice Trench and Ballfield East of Sluice Trench	Refusal	--	Geo
KIF-B16	Sluice Trench and Ballfield East of Sluice Trench	Refusal[1]	--	Geo

Notes:
CCR = Coal Combustion Residuals;
PZ = Piezometric (Pore Water) Levels;
Geo = Geotechnical Data;
No. = Number;
PZ = Piezometric (Pore Water) Levels;
VWP = Vibrating Wire Piezometer
Refusal = indicates rock-like resistance to borehole advancement. This may indicate the beginning of weathered bedrock, boulders, rock remnants, cemented materials, or other hard/dense layers that prevent hole advancement.
[1] Borings KIF-B06, KIF-B07, KIF-B12, KIF-B13, and KIF-B16 were terminated based on field observations by the Stantec PE, without achieving the planned refusal. However, these borings reached weathered rock, which was sufficient to achieve the technical objectives for these borings.

As shown on Exhibit A.3 in Appendix A, a total of 12 borings, including three borings with VWPs, were drilled within or adjacent to the footprint of the Sluice Trench and Ballfield East of Sluice Trench. Borings KIF-B05, KIF-B09 and KIF-B13 each included VWPs and are located along the crest of the East Dike to facilitate material characterization stability analyses. To better characterize the pore water pressures along the dike alignment, six VWPs were installed in these three borings (Exhibit A.4).

The remaining nine borings are located along or near the outboard toe of the East Dike, and were accessed via a barge (i.e., floating plant) to improve spatial coverage for material characterization and to facilitate stability analyses.

3.4 DOCUMENTATION

Stantec maintained EXD field documentation in general accordance with ENV-TI-05.80.03, *Field Record Keeping*, the EXD SAP, and the QAPP. Field documentation for environmental soil sampling activities is described in the CCR Material Characteristics SAR. Health and safety forms were completed in accordance with TVA and Stantec health and safety requirements. Field activities and data were primarily recorded on program-specific field forms. Additional information regarding EXD field documentation is provided below.

3.4.1 Field Forms

Stantec used program-specific field forms to record field observations and data for specific activities. Field forms used during the EXD included:

- *Daily Field Activity Log*
- *Subsurface Log*
- *Chain-of Custody (COC)*
- *Monitoring Well Installation Field Log*
- *Well Development Form*
- *Equipment Calibration Form*
- *Slug Test Data Form*
- *Vibrating Wire Piezometer Installation Notes and Details.*

3.4.1.1 Daily Field Activity Log

Stantec field sampling personnel (FSP) recorded field activities, observations, and data on a *Daily Field Activity Log* to chronologically document the field program. Deviations from the SAP, TIs or QAPP were documented on *the Daily Field Activity Log*.

3.4.1.2 Subsurface Log

A Stantec PG or PE licensed in the State of Tennessee prepared a *Subsurface Log* for each boring. The log documented time, boring location, drilling personnel, tooling/equipment used, depth to pore water, sample number, sample recovery, soil/rock lithology, and other relevant observations. Soil color was logged per the appropriate Munsell Soil Color Chart (Munsell Color 2009). Information from these logs was used to construct the subsurface logs provided in Attachment C.1 in Appendix C.

3.4.1.3 Chain-of-Custody

Stantec FSP completed geotechnical COC documentation for each soil sample collected during the EXD. The sample identification (ID), sample location, sample depth, type of sample, sampling date, and sample custody record were recorded on the COCs. The Field Team Leader reviewed the COCs for completeness, and the FSP conducted a QC check of samples in each shipment compared to sample IDs on the corresponding COC prior to submittal to the laboratory. COCs were completed in general accordance with *ENV-TI-05.80.02: Sample Labeling and Custody*.

3.4.1.4 Monitoring Well Installation Field Log

A Stantec PG licensed in the State of Tennessee prepared a *Monitoring Well installation Field Log* for each temporary well. The log documented the well location, well installation date(s), well installation materials, well depth, screened interval, depth interval for each backfill material, and surface completion details. Information from these logs was used to construct the temporary well installation details provided in Attachment C.2 in Appendix C.

3.4.1.5 Well Development Form

Stantec FSP completed a *Well Development Form* for each temporary well. The form documented well location, well development date(s), elapsed time since development started, depth to pore water, purge rate, cumulative purge volume, and pore water quality parameter measurements throughout and at completion of the development process.

3.4.1.6 Equipment Calibration Form

Stantec FSP performed daily equipment calibrations of the water quality meter and documented the results on an *Equipment Calibration Form*. The form documented the calibration test results for temperature, turbidity, specific conductance, pH, and verified that the field instruments' sensors were operating within acceptable criteria. Refer to Section 3.4.2 for additional details on equipment calibration procedures.

3.4.1.7 Slug Test Data Form

Stantec FSP completed a *Slug Test Data Form* for the hydraulic conductivity tests performed at each temporary well. The form primarily documented well location, slug test date(s), and initial and final pore water level measurements before and after each slug test attempt. The pore water level measurements during the tests were recorded by an automated pressure transducer and data recorder and subsequently downloaded.

3.4.1.8 Vibrating Wire Piezometer Installation Notes and Details

A Stantec PG or PE licensed in the State of Tennessee prepared a *Vibrating Wire Piezometer Installation Notes and Details* log for each boring containing VWPs. The log documented the piezometer location, piezometer installation date(s), borehole depth, piezometer installation materials, transducer calibration

data, quality checks of the transducer(s), transducer depth(s), installation notes, and surface completion details (protective casing, concrete pad, bollards, etc.). Information from these logs was used to construct the piezometer installation details provided in Attachment C.4 in Appendix C.

3.4.2 Equipment Calibration

Field instruments used to collect, generate, or measure water quality parameters data were calibrated each day prior to sampling as specified by the SAP, QAPP, and ENV-TI-05.80.46, *Field Measurement Using a Multi-Parameter Sonde*. Afternoon calibration verifications were performed to evaluate if instruments remained within acceptable criteria during sampling. Temperature and barometric pressure were recorded using a calibrated NIST traceable thermometer and the National Weather Service (via mesowest.utah.edu) barometric pressure readings for Oak Ridge National Laboratory (KOQT), Oak Ridge, Tennessee, respectively. Additional details regarding equipment calibration were recorded on the *Equipment Calibration Form*, as described in Section 3.4.1.6.

3.4.3 Photographs

In addition to documentation of field activities described above, photographs were taken to document the field investigation. Photographic logs of soil samples recovered from Phase 1 borings and site condition photographs including the surface completion of installed temporary wells are provided in Attachments D.1 and D.2, respectively, in Appendix D. Photographic logs of soil samples recovered from Phase 2 borings and site condition photographs including surface completion of installed VWPs are provided in Attachments D.3 and D.4, respectively, in Appendix D.

3.5 DRILLING AND SAMPLING

The following sections present drilling and soil sampling procedures used during the EXD. Drilling and sampling activities were performed under the direction of a Stantec PG or PE licensed in the State of Tennessee.

3.5.1 Drilling

Drilling, sampling, temporary well installation and VWP installation was performed by Stantec drillers licensed in Tennessee, using Stantec equipment. Supplemental drilling and sampling, utilizing direct push technology, was performed by Hawkston Drilling, LLC, licensed in Tennessee and under subcontract to Stantec, with field oversight and logging by Stantec. Borings were drilled in areas with drive-on access; no special site preparations were necessary to facilitate access.

Hollow stem auger borings were advanced by means of continuous split-spoon (SS) sampling to recover soil for lithologic description, photographic documentation, and sample collection. Each run was then overdrilled using 4.25-inch hollow stem augers. After reaching the bottom of borehole, the 4.25-inch hollow stem augers were withdrawn. The upper portion of the borehole was overdrilled with 8.25-inch (inside diameter) hollow-stem augers to ream the borehole to a larger diameter, to facilitate subsequent installation of the temporary well. Hollow stem augers were decontaminated using a high-pressure steam cleaner and potable water after use at each boring. At each direct push boring location, the boring was

advanced by means of a dual tube sampling system with a closed point tip (i.e., drilling without sampling) to approximately five feet above the termination depth of the adjacent temporary well location. The closed point tip was removed through the casing and a DT37 lined sampler was used to begin continuously sampling the CCR until encountering approximately five feet of the uppermost foundation soils. Direct push borings were advanced in either 2.5- or five-foot runs to recover soil for lithologic description, photographic documentation, and sample collection. Supplemental borings KIF-B01a, KIF-B01b, KIF-B02a, KIF-B02b, KIF-B03a and KIF-B03b penetrated the engineered soil cap of the Interim Ash Staging Area. Boring KIF-B04a penetrated the engineered soil cap of the Sluice Trench area. After the DPT borings were performed, they were backfilled to approximately two feet below the ground surface with 30% solids bentonite grout. The upper 2 feet of the borings were backfilled with clayey soil from an onsite source.

Phase 2 EXD geotechnical borings were advanced by a combination of hollow-stem auger and mud rotary drilling techniques. Mud rotary drilling was conducted in general accordance with American Society for Testing and Materials (ASTM) D5783. The borings were advanced by means of SS and/or undisturbed (Shelby) tube (ST) sampling to recover soil for lithologic description, photographic documentation, and sample collection. Each run was then overdrilled using a mud rotary updraft roller bit.

To support seismic analyses, the automatic hammer used for Standard Penetration Testing during the Phase 2 EXD was subjected to energy verification testing per ASTM D4633. Energy verification testing was performed in boring KIF-B05. A summary of the test data and results of the automatic hammer energy verification is presented in Attachment E.2 in Appendix E.

A summary of the as-drilled boring depths, elevations, and types of sampling or testing is presented in Tables B.1 and B.7 in Appendix B. Boring locations are included on Exhibits A.2 and A.3 in Appendix A.

3.5.2 Soil Sampling

During advancement of each boring, the Stantec PG or PE prepared field subsurface logs using a mobile data collection platform. Inputs included a description of subsurface lithology, sample recovery, color using the Munsell Soil Color Chart, and other relevant parameters as required by the SAPs and TIs. Subsurface logs for the KIF Plant EXD are presented in Attachments C.1 (for Phase 1) and C.3 (for Phase 2) in Appendix C.

Soil samples were collected from each boring to provide lithologic information for a continuous subsurface log/soil profile for the proposed temporary wells. Temporary well borings (including KIF-TW03a and KIF-TW03b) were advanced using a conventional rotary drill rig with SS and ST sampling. Two-inch and/or three-inch diameter split-spoons were used to collect disturbed SS soil samples. SS and ST samples were collected for general soil and CCR characterization and potential laboratory testing. Three-inch diameter tubes were used to collect undisturbed ST soil samples. During Phase 1 EXD, the tubes were advanced using a standard ST sampler or a fixed piston sampler. Supplemental borings were advanced using a DPT drill rig. Dual tube soil samples were collected for general soil and CCR characterization along with potential laboratory testing. During Phase 2 EXD, the tubes were advanced using a fixed piston sampler or a hydraulic fixed piston sampler (i.e., Osterberg sampler). SS and ST samples were

collected for general soil and CCR characterization and potential laboratory testing. Each drill rig employed for in-situ penetration testing utilized an automatic hammer. The hammer weight and/or drop height may vary based on the drill rig, sampler size, and the sampling objectives of each boring.

Tables B.2 and B.8 in Appendix B summarize the soil samples collected in each boring along with sampler and hammer information. No rock coring or downhole testing in rock were performed for the units at the KIF Plant as part of the EXD. The subsurface logs in Attachments C.1 and C.3 record the depths of the recovered samples along with the results of the in-situ penetration testing program, including field blow counts.

For the Phase 1 and 2 work, select soil samples collected during the EXD were subjected to geotechnical laboratory testing. Select SS and ST samples were subjected to Unified Soil Classification System classification and index testing including natural moisture content, gradation, Atterberg limits, and specific gravity tests. Additionally, select ST samples from the Phase 1 drilling were subjected to triaxial compression and hydraulic conductivity tests. Not all test types were performed on all encountered materials. Tests were assigned based on material recovery, availability, and subsurface characterization needs. Appendix F presents the Phase 1 and 2 geotechnical laboratory testing results for select soil samples. Attachment F.1 (Tables F.1-1 through F.1-7) in Appendix F presents summaries of the Phase 1 geotechnical laboratory testing results for select soil samples. Attachment F.6 (Tables F.6-1 through F.6-4) in Appendix F presents summaries of the Phase 2 geotechnical laboratory testing results for select soil samples. The laboratory data sheets for each specific test are provided in Attachments F.2 through F.5 for Phase 1, and Attachments F.6 through F.8 for Phase 2.

3.5.3 Sample Shipment

At appropriate intervals, assigned personnel transported the geotechnical samples to the testing laboratory or designated storage facility. A geotechnical *COC* accompanied the samples throughout the shipping process.

SS and DPT samples are disturbed samples and were treated as Group B samples as discussed in ASTM D4220. The Shelby tubes were stored vertically in padded racks constructed in accordance with ASTM D4220. Based on anticipated weather conditions during sampling operations, care was taken in the storage of the samples to guard against the samples being exposed to extreme heat or cold. Prior to transport, the tubes were transferred to a custom box built in accordance with ASTM D4220 guidelines for transporting Group D type soil samples.

3.6 TEMPORARY WELL INSTALLATION

3.6.1 Temporary Well Installation

Temporary wells were installed in the borings by qualified drill crews working under the direction of a Stantec PG and a licensed Tennessee driller. Temporary well installation was carried out in general accordance with ENV-TI-05.80.25, *Monitoring Well and Piezometer Installation and Development*.

Temporary well construction details are documented on the Well Installation Detail sheets provided in Attachment C.2 in Appendix C.

The lowest portions of the borings were backfilled with bentonite pellets, then generally topped with a layer of sand filter pack (20/40 mesh). The temporary well was installed above the backfilled portion. Temporary wells consisted of a four-inch diameter Schedule 40 polyvinyl chloride (PVC) pre-packed well screen (0.010-inch slots) and riser. The screen and riser consisted of flush-joint, threaded PVC pipe. The screen length was nominally 10 feet. The PVC riser extended a minimum of 2.5 feet above the ground surface and was capped with a temporary plug or slip cap. The annular space was backfilled with a sand filter pack extending approximately two feet above and six inches below the screen. A bentonite pellet seal approximately two feet thick was placed on top of the sand filter pack. The sand filter pack and bentonite pellets were either placed by tremie method or poured slowly into the annular space of the drill tooling to prevent bridging.

After the bentonite pellet seal had sufficiently hydrated for a duration equal to or greater than the minimum recommended by the manufacturer (a minimum of four hours), the remaining annular space was backfilled with a 30% solids bentonite grout. The grout was placed by tremie method through one-inch or 1.5-inch diameter PVC pipe using pumps gauged to allow the installation crew to monitor pressures during the grouting process.

Borings KIF-TW01, KIF-TW02 and KIF-TW03 (including KIF-TW03a, KIF-TW03b and KIF-TW03ALT, see Section 3.11) penetrated the engineered soil cap of the Interim Ash Staging Area. Boring KIF-TW04 penetrated the engineered soil cap of the Sluice Trench area. Borings KIF-TW03a and KIF-TW03b encountered obstructions, did not have a temporary well installed, and were backfilled using 30% solids bentonite grout to within two feet of the ground surface. The uppermost two feet of Borings KIF-TW03a and KIF-TW03b were backfilled with clayey soil from an onsite source. After temporary wells KIF-TW01 through KIF-TW04 were installed, the annular space of the uppermost portion of each boring was backfilled using 30% solids bentonite grout.

Boring KIF-TW05 was performed in an area of the Sluice Trench and Ballfield East of Sluice Trench that was in the process of being capped and closed as part of a separate TVA project. The final cap included geosynthetics and soil components. TVA coordinated the drilling and closure activities such that the temporary well was installed, and the closure contractor followed by attaching the geomembrane to the KIF-TW05 riser pipe using a temporary pipe boot and placing the final cover soil. If/when it is decided to abandon the temporary well in the future (per the EIP), TVA will coordinate removal of the boot and repair of the final cap.

As allowed in the EXD SAP, TVA elected to modify the surface protection for each of the five temporary well installations. Instead of installing a concrete well pad and steel protective cover, TVA installed temporary fence posts and plastic fencing around each riser pipe. Fence posts were not driven deep enough to fully penetrate the final caps. A summary of temporary well installations is presented in Table B.3 in Appendix B. Construction details are presented in the Temporary Well Installation Details provided in Attachment C.2 in Appendix C.

3.6.2 Temporary Well Development

Each new temporary monitoring well was developed in accordance with ENV-TI-05.80.25, *Monitoring Well and Piezometer Installation and Development* by a combination of bailing, surging, and pumping after a minimum of 24 hours following temporary well installation. First, a three-inch diameter PVC bailer was lowered and raised within the screened intervals to create a slight surging action to dislodge particles within the temporary wells and sand filter packs. Then the bailer was used to remove turbid pore water from the temporary well. Baseline readings of turbidity, pH, temperature, and specific conductance were measured using a calibrated YSI Pro Plus water quality meter and a calibrated Hach 2100Q turbidity meter. This process of alternately surging and bailing was repeated several times to decrease the pore water turbidity within the temporary wells. Lastly, a submersible pump was employed to further develop the temporary wells until stabilization criteria for turbidity (≤10 Nephelometric Turbidity Units), pH (±0.1 Standard Unit), temperature (±10%), and specific conductance (±10%) were achieved. The target turbidity value was based on well purging criteria specified in ENV-TI-05.80.42, *Groundwater Sampling* at the time of development. Temporary well development details were recorded on the *Well Development Form.*

Typically, development continued over a span of two to six hours, although development of two temporary wells continued into a second day. Recharge rates observed within the temporary wells near the conclusion of development ranged from 1.7 gallons per hour (gal/hr) at temporary well KIF-TW02 to 6.2 gal/hr at temporary well KIF-TW01. Stabilization criteria were achieved for turbidity, specific conductance, pH, and temperature in each temporary well at completion of development. A summary of initial and final pore water quality measurements is presented in Table B.4 in Appendix B.

3.6.3 Hydraulic Conductivity (Slug) Testing

After development, Stantec performed slug tests in the five temporary wells to estimate hydraulic conductivity. The slug tests were performed in accordance with the ASTM D4044: *Standard Test Method for (Field Procedure) for Instantaneous Change in Head (Slug) Tests for Determining Hydraulic Properties of Aquifers*. A pressure transducer with a data recorder was used to collect pore water level information from the temporary wells.

Three to four rising-head and three to four falling-head slug tests were performed at each temporary well, as shown on Table B.5 in Appendix B. Each temporary well was tested by taking an initial measurement of the static pore water level followed by the insertion of the pressure transducer into the temporary well. After the transducer had been installed, a falling-head slug test was conducted by introducing a solid slug (e.g., PVC pipe filled with sand) into the temporary well to cause a nearly instantaneous rise in the pore water level. The pore water levels were then recorded at regular intervals until reaching near initial static levels. After the first test concluded, a rising-head slug test was conducted by removing the slug to cause a nearly instantaneous drop in the pore water level. Pore water levels were recorded until initial static pore water levels were reached again. The procedure of alternating a falling-head and a rising-head slug test was conducted at least three times at each temporary well. The data were recorded electronically by the transducer and downloaded into a data collector. Raw data were checked in the field for discrepancies prior to demobilizing from the KIF Plant.

The field data were analyzed using AQTESOLV™ Version 4.50 Professional software to estimate the hydraulic conductivity of the saturated soils in the screened interval. Calculated hydraulic conductivities are summarized in Table B.5 in Appendix B, and the full software output package is provided in Appendix E.

Specific to the KIF Plant temporary wells, analysis for each was completed using the Bouwer-Rice method. The solution was matched to the normalized plotted recovery data between 70-80% recovery.

3.7 INSTRUMENTATION INSTALLATION

VWPs were installed in the borings by qualified drill crews working under the direction of a Stantec PG or PE. VWP construction details are documented on the Piezometer Installation Detail sheets provided in Attachment C.4 in Appendix C.

After completion of the boring, the number of VWP transducers and installation depths were selected based on observed subsurface conditions and EXD objectives. Each VWP transducer was checked and prepared per the manufacturer recommendations, prior to installation. Hollow-stem augers were left in place to keep the borehole open and the depth to the bottom of the borehole was measured. A sacrificial tape was then affixed to a sacrificial Schedule 40 PVC pipe in order to attach the VWPs and lower to the desired depth(s) in the borehole. The hollow-stem augers were removed as the borehole was backfilled with 30% solids bentonite grout through the sacrificial pipe. At the surface, excess cable from each VWP was coiled and placed in a five-gallon bucket for protection.

The VWPs installed in borings KIF-B05 and KIF-B09 are located in proximity to existing monitoring wells KIF-106 and AD-2, respectively. From one hour before to one hour after grouting of KIF-B05 and KIF-B09, the groundwater levels were monitored in KIF-106 and AD-2 (respectively) to evaluate possible grout-related influence on the water levels. In both cases, the fluctuations in groundwater levels were less than ±0.02 feet, and were considered negligible. Three weeks following the completion of grouting activities in both borings, groundwater field parameters (water level, temperature, pH, specific conductance, dissolved oxygen, oxidation reduction potential, and turbidity) were recorded in the two monitoring wells to evaluate possible grout-related impacts to the groundwater quality. The field parameters were collected every three to five minutes, until the stabilization criteria were met. The procedures followed applicable portions of Section 5.2 of the *Groundwater Investigation SAP* (Stantec 2018e). Available field parameter data from previous groundwater sampling events at KIF-106 and AD-2 were used to represent the existing conditions prior to grouting. Compared to the pre-grouting data, the post-grouting field parameters were within range of the natural system variability observed for each of the two wells. Therefore, no grout-related impacts were apparent.

As allowed in the EXD SAP, TVA elected to modify the surface protection for each of the VWP installations. Instead of installing a concrete pad and steel protective cover, Stantec installed temporary surface protection (fence posts and plastic fencing) around each riser pipe.

A map showing piezometer locations and the material(s) monitored is provided on Exhibit A.4 in Appendix A. A summary of VWP installations is presented in Table B.9 in Appendix B. Construction details are presented in the Piezometer Installation Details provided in Attachment C.4 in Appendix C.

3.8 INVESTIGATION DERIVED WASTE

Investigation derived waste (IDW) generated during EXD included:

- Soil cuttings
- Used calibration solutions
- Temporary well development water
- Decontamination fluids
- Personal protective equipment (PPE)
- General trash.

IDW was handled in general accordance with ENV-TI-05.80.05, *Field Sampling Equipment Cleaning and Decontamination*; ENV-TI-05.80.25, *Monitoring Well and Piezometer Installation and Development*; the EXD SAP; the KIF Plant-specific waste management plan; and local, state, and federal regulations. Transportation and disposal of IDW were coordinated with the KIF Plant facility management. Soil cuttings, decontamination fluids, and temporary well development water were managed as authorized by the KIF Plant facility management and in accordance with the EXD SAP. Used disposable PPE (e.g., nitrile gloves) and general trash were placed in garbage bags and disposed of in a municipal waste dumpster onsite.

3.9 BORING AND TEMPORARY WELL SURVEYS

After the temporary wells were installed, they were professionally surveyed by The RLS Group, LLC, on May 2, 2019 under subcontract to Stantec. Boring locations for KIF-TW03a and KIF-TW03b are based on handheld global positioning system (GPS) coordinates at the time of drilling. After the supplemental borings were performed, they were professionally surveyed by TVA on January 9, 2020. Measurements were calculated relative to the coordinate systems used by the KIF Plant. Phase 1 temporary well and boring survey information is provided in Table B.6 in Appendix B.

For each Phase 2 boring drilled from the barge, the top of temporary casing location was surveyed by Stantec prior to moving to the next boring location. The horizontal coordinates were acquired using a handheld GPS with sub-meter accuracy. The vertical coordinates were acquired using differential leveling techniques, relative to a temporary benchmark on the East Dike. Phase 2 borings drilled on the land were professionally surveyed by TVA on March 4, 2021. Measurements were calculated relative to the coordinate systems used by the KIF Plant. Phase 2 boring survey information is provided in Table B.10 in Appendix B.

3.10 BATHYMETRIC SURVEY

A bathymetric survey was performed by TVA within the Intake Channel adjacent to East Dike. The bathymetric survey was conducted to identify the top of sediment/soil beneath the water, within the specified horizontal extents of the survey. Methods included sonar and physical soundings (rod, weighted tape, etc.). Horizontal and vertical coordinates of the survey data were referenced to the horizontal and vertical datums used by the KIF Plant. Appendix G includes a contour map for elevations of the top of sediment/soil within the limits of the bathymetric survey.

3.11 VARIATIONS

The proposed scope and procedures for the EXD were outlined in the SAP, QAPP, applicable TVA TIs, and ASTM standards, as detailed in the sections above. Variations in scope or procedures discussed with TDEC and/or TVA, changes based on field conditions, or additional field sampling performed to complete the scope of work in the SAP are described in the following sections. As discussed below, these variations do not impact the overall usability and representativeness of the dataset provided in this SAR for the EXD activities at the KIF Plant.

3.11.1 Variations in Scope

Variations in scope are provided below.

- During the EXD, the crew relocated KIF-TW03 (following TDEC approval) after encountering rock fill within the footprint of a decommissioned chemical treatment pond that was within the larger footprint of the Interim Ash Staging Area. The initial location (later designated KIF-TW03a) was sampled and drilled to a depth of 15.3 feet, at which point the boring was terminated and backfilled due to encountering rock fill. An offset boring (KIF-TW03b) was attempted 20 feet to the west of KIF-TW03a. Again, refusal was encountered in the rock fill at a depth of 13.5 feet and the boring was terminated and backfilled. After additional review of historical documents, the final location for KIF-TW03 (drilled at the KIF-TW03ALT location) was selected outside of the former chemical treatment pond footprint. TDEC approval was obtained for the final location, the boring was successfully completed, and temporary well KIF-TW03 was installed.

- After the completion of drilling and laboratory testing of samples from the temporary well borings, review of the data showed that borings KIF-TW01 through KIF-TW04 did not reach the foundation soils as originally logged in the field. These borings were inadvertently terminated within the CCR. Therefore, the supplemental direct push borings were added to extend the material profiles into the foundation soils and obtain the deeper samples adjacent to temporary wells KIF-TW01 through KIF-TW04. During the supplemental drilling, boring KIF-B04b was determined not to be necessary since adequate information and sample volume were obtained from boring KIF-B04a.

- Borings KIF-B06, KIF-B07, KIF-B12, KIF-B13 and KIF-B16 were terminated based on field observations by the Stantec PE, without achieving the planned refusal. However, these borings

reached weathered rock, which was sufficient to achieve the technical objectives for these borings.

- Groundwater field parameters were not monitored in KIF-106 and AD-2 during grouting of KIF-B05 and KIF-B09 (respectively) because purging of the wells would have interfered with a scheduled groundwater sampling event. Instead, TDEC and TVA agreed that it would be adequate to only monitor water levels in the wells during grouting. The post-grouting field parameter monitoring was performed three weeks after grouting, instead of the planned seven to ten days, to avoid interfering with the scheduled groundwater sampling event.

3.11.2 Variations in Procedures

Variations in procedures occurring in the field are provided below.

- During installation of temporary well KIF-TW05, well seal and grouting procedures differed from those described in the SAP, with bentonite pellets used for the well seal hydrated for two hours prior to placing bentonite grout in the annular space above the seal. Although the manufacturer's specifications suggest a minimum pellet hydration time of four hours, an appropriate well seal and grouting was achieved at temporary well KIF-TW05.

- Well seal type and grouting procedures used during temporary well installation were modified to allow for the use of a bentonite grout and to account for manufacturer's specifications. Revised procedures were approved by TDEC and appropriate well seals and grouting were achieved at each temporary well.

- Photographs of soil samples from borings KIF-TW03a and KIF-TW03b were taken in the field. However, the digital photographs were lost prior to file storage. Soil lithologies were described in subsurface logs as provided in Appendix C.

3.12 LIMITATIONS

The methods and locations of the subsurface exploration considered objectives of the EIP, available historical data, and input from TVA and TDEC. The subsurface exploration was developed to address specific data gaps, as outlined in the EIP. The methods used in this field exploration include inherent limitations as described below.

- The information presented herein was gathered from the borings advanced during this exploration using that degree of care and skill ordinarily exercised under similar circumstances by competent members of the engineering profession. However, no warranties can be made regarding the continuity of conditions between borings.

- The subsurface logs describe subsurface conditions at the specific locations at the time of drilling. Pore water levels may fluctuate over time with adjacent reservoir water level, weather conditions, and/or other influences.

4.0 SUMMARY

The data presented in this report are from the Phase 1 and Phase 2 EXD activities at the KIF Plant.

4.1 PHASE 1 EXPLORATORY DRILLING

The Phase 1 EXD included a total of seven auger borings and seven direct push borings. Five of the auger borings included temporary well installations. The borings were implemented to improve spatial coverage for CCR thickness, uppermost foundation soil type, and pore water levels within the CCR units at the time of drilling. The scope of work for Phase 1 EXD included:

- Drilled five auger borings and six direct push borings within the Interim Ash Staging Area
- Drilled two auger borings and one direct push boring within the Sluice Trench and Ballfield East of Sluice Trench
- Collected soil samples to develop a continuous subsurface log/soil profile for each boring, with select soil samples subjected to geotechnical laboratory testing
- Installed temporary wells in five of the auger borings (three in the Interim Ash Staging Area, two in the Sluice Trench and Ballfield East of Sluice Trench) and constructed surface protections
- Developed each temporary well and conducted slug testing to estimate hydraulic conductivity
- Surveyed each new boring and temporary well.

A summary of the Phase 1 EXD performed in each CCR unit is presented in Table 1. A summary of the Phase 1 EXD borings, including CCR unit and borehole termination criteria, are presented in Table 2. Phase 1 boring summary, soil and rock sample summary, temporary well construction details, temporary well development, hydraulic slug testing results, and survey information are presented in Tables B.1 through B.6, respectively. Phase 1 subsurface logs and temporary well installation details are located in Attachment C.1 and Attachment C.2, respectively. Phase 1 geotechnical laboratory testing results for select soil samples are presented in Attachments F.1 through F.5.

Phase 1 EXD activities were carried out concurrently with CCR material sampling and pore water monitoring and sampling, which were performed in accordance with the CCR Material Characteristics and Material Quantity SAPs. Refer to the CCR Material Characterization and Material Quantity SARs for information from those concurrent activities.

4.2 PHASE 2 EXPLORATORY DRILLING

The Phase 2 EXD included a total of 12 geotechnical borings. Three of the borings included VWP installations. The borings were implemented to improve subsurface characterization in support of upcoming stability analyses. The scope of work for Phase 2 EXD included:

- Performed a bathymetric survey within the Intake Channel adjacent to the East Dike
- Drilled 12 borings within the Sluice Trench and Ballfield East of Sluice Trench
- Collected soil samples to develop a subsurface log/soil profile for each boring, with select soil samples subjected to geotechnical laboratory testing
- Installed VWPs in three of the borings and constructed surface protections
- Surveyed each new boring location.

A summary of the Phase 2 EXD performed in each CCR unit is presented in Table 3. A summary of the Phase 2 EXD borings, including CCR unit and borehole termination criteria, are presented in Table 4. Phase 2 boring summary, soil and rock sample summary, VWP construction details, and survey information are presented in Tables B.7 through B.10, respectively. Phase 2 subsurface logs and VWP installation details are located in Attachment C.3 and Attachment C.4, respectively. Phase 2 geotechnical laboratory testing results for select soil samples are presented in Attachments F.6 through F.8. A contour map for the top of sediment/soil within the limits of the bathymetric survey is presented in Appendix G.

4.3 CLOSING

Stantec has completed the EXD at the KIF Plant in Roane County, Tennessee, in accordance with the EXD SAP and EXD SAP Addendum as documented herein. The data collected during the EXD are usable for reporting and evaluation in the EAR and meet the objectives of the TDEC Order EIP. EXD boring, temporary well installation, and VWP installation data will be evaluated along with data collected under other SAPs, including but not limited to, the CCR materials characteristics and CCR material quantity investigations. This evaluation will be provided in the EAR.

KIF-B03b	776.5	722.0	NR	716.5	60.0	60.0	DP
KIF-B04a	765.5	721.5	NR	715.5	50.0	50.0	DP

Notes:

bgs	below ground surface	N/A	Not Applicable
CCR	coal combustion residuals	NGVD29	National Geodetic Vertical Datum of 1929
Elev.	elevation	NR	No Refusal
DP	direct push (2” diameter)	SS	split-spoon (2” or 3”, refer to boring log for sampler size)
ft	feet	ST	undisturbed thin-walled Shelby tube
ID	identification		

1. Ground surface elevations listed are as-drilled elevations.
2. Refusal indicates rock-like resistance to boring advancement. This may indicate the beginning of weathered bedrock, boulders, rock remnants, cemented materials, or other hard/dense layers that prevent hole advancement.
3. KIF-TW03a and KIF-TW03b were attempted at the KIF-TW03 location referenced in EIP Rev. 4. However, the temporary well could not be installed at this location.
4. KIF-TW03 was drilled at the KIF-TW03ALT location referenced in EIP Rev. 4.

1. Borings KIF-B05, KIF-B09, and KIF-B13 were surveyed by TVA on 3/4/2021. For borings KIF-B06 through KIF-B08, KIF-B10 through KIF-B12, and KIF-B14 through KIF-B16, the top of temporary casing location was surveyed by Stantec prior to moving to the next boring location. State Plane coordinates rounded to the nearest 0.01 feet. Latitude and Longitude rounded to the nearest 0.01 second. Ground surface elevations rounded to the nearest 0.1 feet.

2. Horizontal coordinates surveyed by Stantec were acquired using a handheld global positioning system with sub-meter accuracy. The vertical coordinates were acquired using differential leveling techniques, relative to a temporary benchmark on the East Dike.

3. Top of casing elevations correlate to a depth of zero on the boring logs, for borings drilled from the barge.

Stantec

General Notes

The boring logs include sample numbering used during drilling. For assigned Environmental Analytical Sample ID numbers, see relevant Environmental Chain-of- Custody forms from the drilling date range listed on each log.

For pH readings and additional field data, see applicable field documentation (e.g., Soil pH Data Form) from the drilling date range listed on each log.

Other Graphics

Symbol	Description
	Denotes environmental analytical sample interval
	Denotes SS sample interval
	Denotes ST sample interval
	Denotes DP sample interval
	Denotes RS sample interval
	Denotes RC sample interval
	First water level reading
	Second water level reading

Common Abbreviations

Abbreviation	Definition
DP	Direct Push
HA	Hand Auger
HSA	Hollow Stem Auger
N/A	Not Applicable
NR	Not Recorded
RC	Rock Core
RQD	Rock Quality Designation
RS	Rotary Sonic
SS	Split Spoon
ST	Shelby Tube
WH	Weight of Hammer
WR	Weight of Rod

General Notes

The boring logs include sample numbering used during drilling. For assigned Environmental Analytical Sample ID numbers, see relevant Environmental Chain-of- Custody forms from the drilling date range listed on each log.

For pH readings and additional field data, see applicable field documentation (e.g., Soil pH Data Form) from the drilling date range listed on each log.

Refusal /
Bottom of Hole at 35.3 Ft.

Top of Rock = 34.0 Ft.
Top of Rock Elevation = 705.3 Ft.

Horizontal coordinates collected at time of drilling using Trimble Geo7x handheld unit. Surface elevation shown reflects the top of steel casing. Top of casing elevation was measured using automatic level and level rod referenced from temporary benchmark established by TVA. The temporary benchmark referenced for KIF-B08 was set at the SW corner of the KIF-106 concrete pad.

1: E = Environmental Sample Custody (two Split Spoons may be required to obtain sufficient sample)
G = Geotechnical Sample Custody
2: a,b,c denote Split Spoon divided between Environmental and Geotechnical Samples
3: Depths are reported in feet below ground surface

Shale, dark brown to dark gray, very fine grained, very soft, highly weathered, 45° bedding angle

No Refusal /
Bottom of Hole at 36.3 Ft.

Top of Rock = 35.3 Ft.
Top of Rock Elevation = 703.9 Ft.

Horizontal coordinates collected at time of drilling using Trimble Geo7x handheld unit. Surface elevation shown reflects the top of steel casing. Top of casing elevation was measured using automatic level and level rod referenced from temporary benchmark established by TVA. The temporary benchmark referenced for KIF-B12 was set at the SW corner of the KIF-AD-2 concrete pad.

No Refusal /
Bottom of Hole at 29.3 Ft.

Horizontal coordinates collected at time of drilling using Trimble Geo7x handheld unit. Surface elevation shown reflects the top of steel casing. Top of casing elevation was measured using automatic level and level rod referenced from temporary benchmark established by TVA. The temporary benchmark referenced for KIF-B16 was set at the NE corner of the KIF-105 concrete pad.

1: E = Environmental Sample Custody (two Split Spoons may be required to obtain sufficient sample)
G = Geotechnical Sample Custody
2: a,b,c denote Split Spoon divided between Environmental and Geotechnical Samples
3: Depths are reported in feet below ground surface

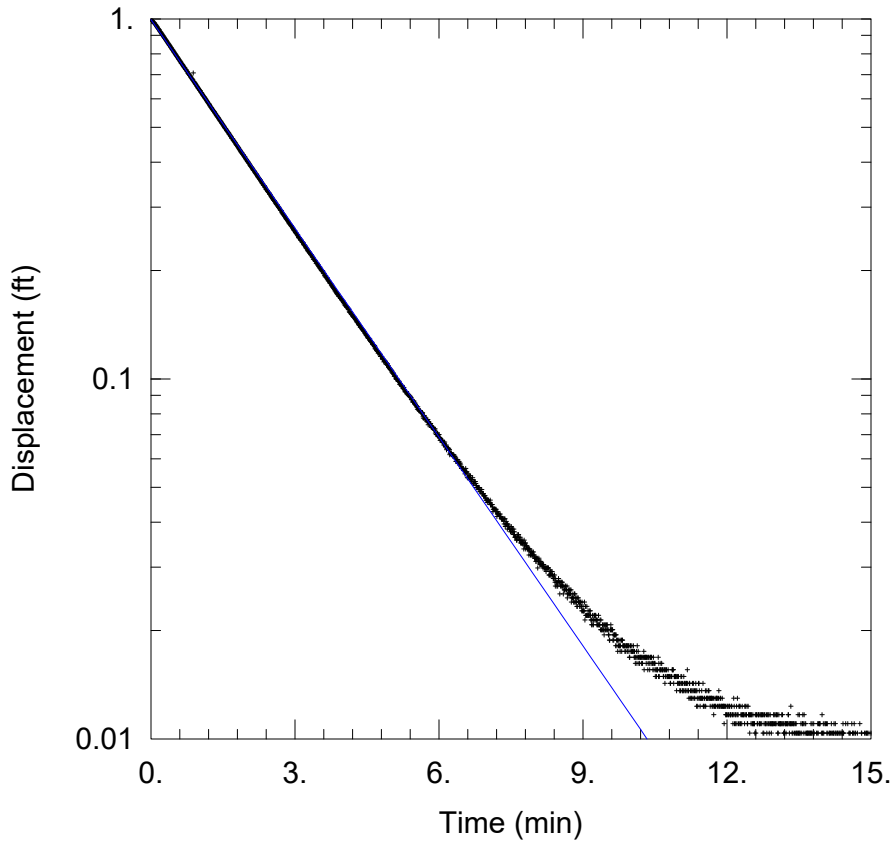
Notes

ft/day - feet per day

cm/sec - centimeters per second

Data analysis was completed using AQTESOLV™, Version 4.50 Professional



TW01 FH TEST 1

Data Set: Z:\...\TW01_FH-T1.aqt
Date: 09/26/19 Time: 11:23:52

PROJECT INFORMATION

Company: Stantec
Client: TVA-KIF
Project: 175668043
Location: Kingston Fossil Plant
Test Well: TW01
Test Date: 06/18/19

SOLUTION

Aquifer Model: Unconfined
Solution Method: Bouwer-Rice

K = 3.353 ft/day
y0 = 0.9959 ft

AQUIFER DATA

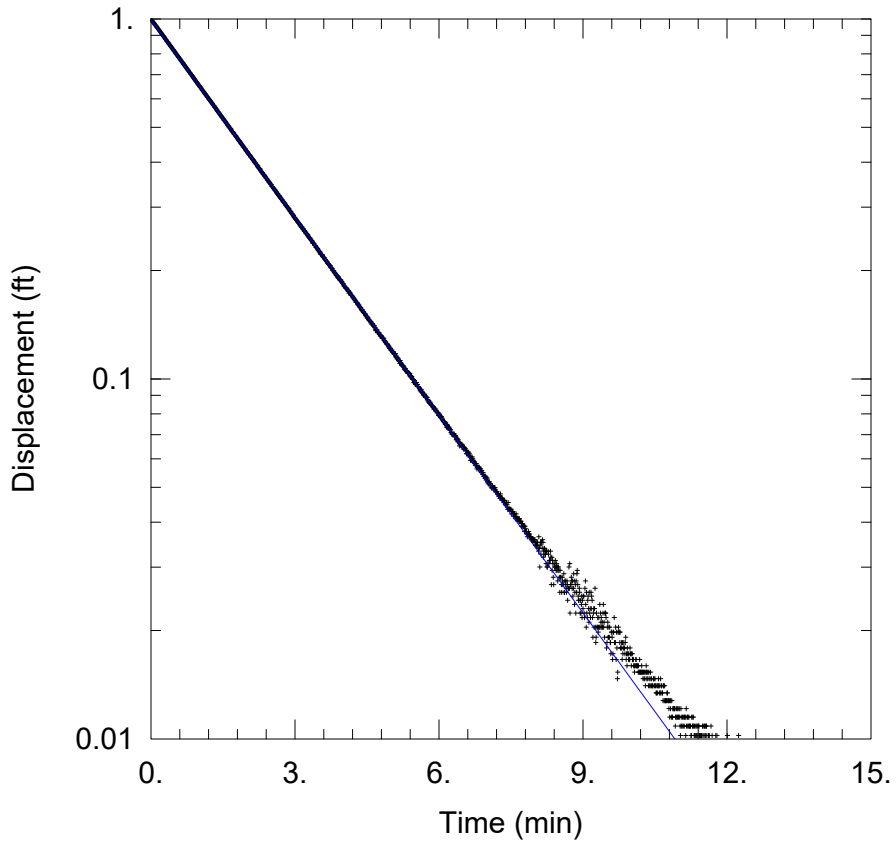
Saturated Thickness: 20.9 ft

Anisotropy Ratio (Kz/Kr): 0.1

WELL DATA (TW01)

Initial Displacement: 1. ft
Total Well Penetration Depth: 20.4 ft
Casing Radius: 0.1667 ft

Static Water Column Height: 20.9 ft
Screen Length: 10. ft
Well Radius: 0.333 ft



TW01 FH TEST 2

Data Set: Z:\...\TW01_FH-T2.aqt
Date: 09/26/19 Time: 11:23:12

PROJECT INFORMATION

Company: Stantec
Client: TVA-KIF
Project: 175668043
Location: Kingston Fossil Plant
Test Well: TW01
Test Date: 06/18/19

SOLUTION

Aquifer Model: Unconfined
Solution Method: Bouwer-Rice

K = 3.175 ft/day
y0 = 0.9946 ft

AQUIFER DATA

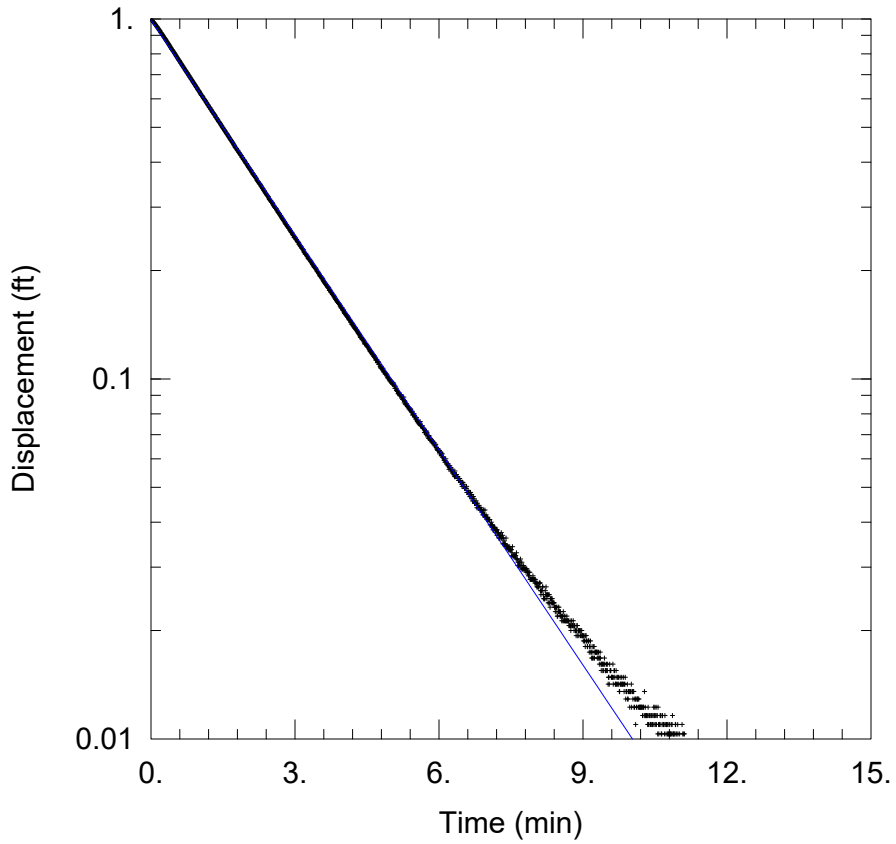
Saturated Thickness: 20.9 ft

Anisotropy Ratio (Kz/Kr): 0.1

WELL DATA (TW01)

Initial Displacement: 1. ft
Total Well Penetration Depth: 20.4 ft
Casing Radius: 0.1667 ft

Static Water Column Height: 20.9 ft
Screen Length: 10. ft
Well Radius: 0.333 ft



TW01 FH TEST 3

Data Set: Z:\...\TW01_FH-T3.aqt
Date: 09/26/19 Time: 11:22:08

PROJECT INFORMATION

Company: Stantec
Client: TVA-KIF
Project: 175668043
Location: Kingston Fossil Plant
Test Well: TW01
Test Date: 06/18/19

SOLUTION

Aquifer Model: Unconfined
Solution Method: Bouwer-Rice

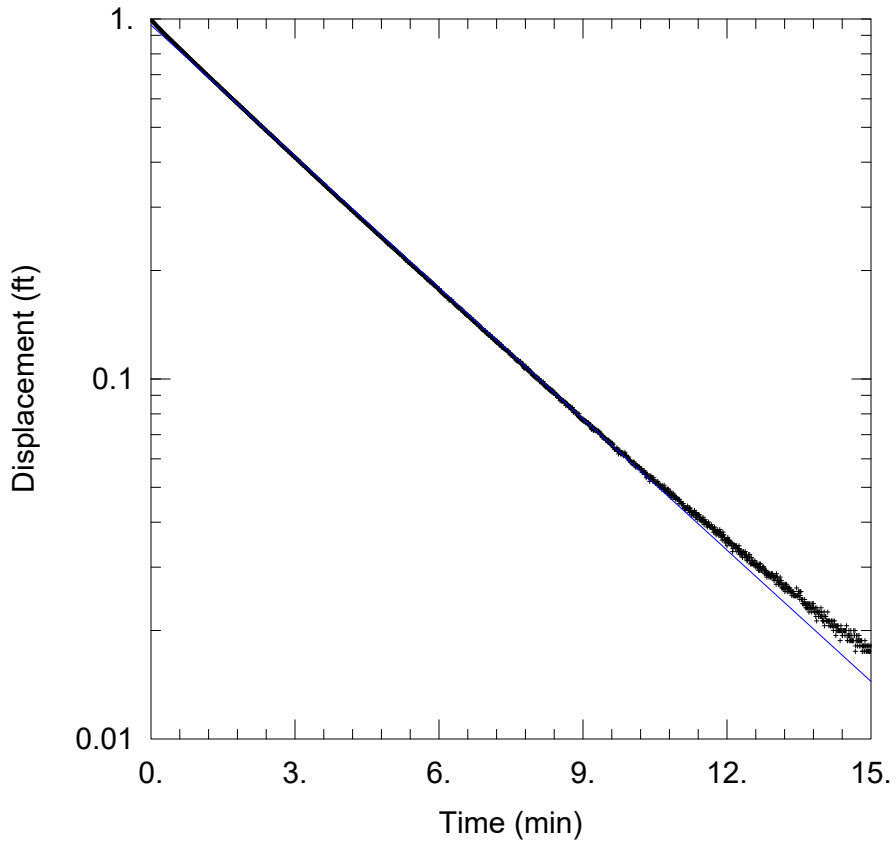
K = 3.453 ft/day
y0 = 0.9927 ft

AQUIFER DATA

Saturated Thickness: 20.9 ft
Anisotropy Ratio (Kz/Kr): 0.1

WELL DATA (TW01)

Initial Displacement: 1. ft
Total Well Penetration Depth: 20.4 ft
Casing Radius: 0.1667 ft
Static Water Column Height: 20.9 ft
Screen Length: 10. ft
Well Radius: 0.333 ft



TW01 RH TEST 1

Data Set: Z:\...\TW01_RH-T1.aqt
Date: 09/26/19 Time: 11:18:36

PROJECT INFORMATION

Company: Stantec
Client: TVA-KIF
Project: 175668043
Location: Kingston Fossil Plant
Test Well: TW01
Test Date: 06/18/19

SOLUTION

Aquifer Model: Unconfined
Solution Method: Bouwer-Rice

K = 2.108 ft/day
y0 = 0.9614 ft

AQUIFER DATA

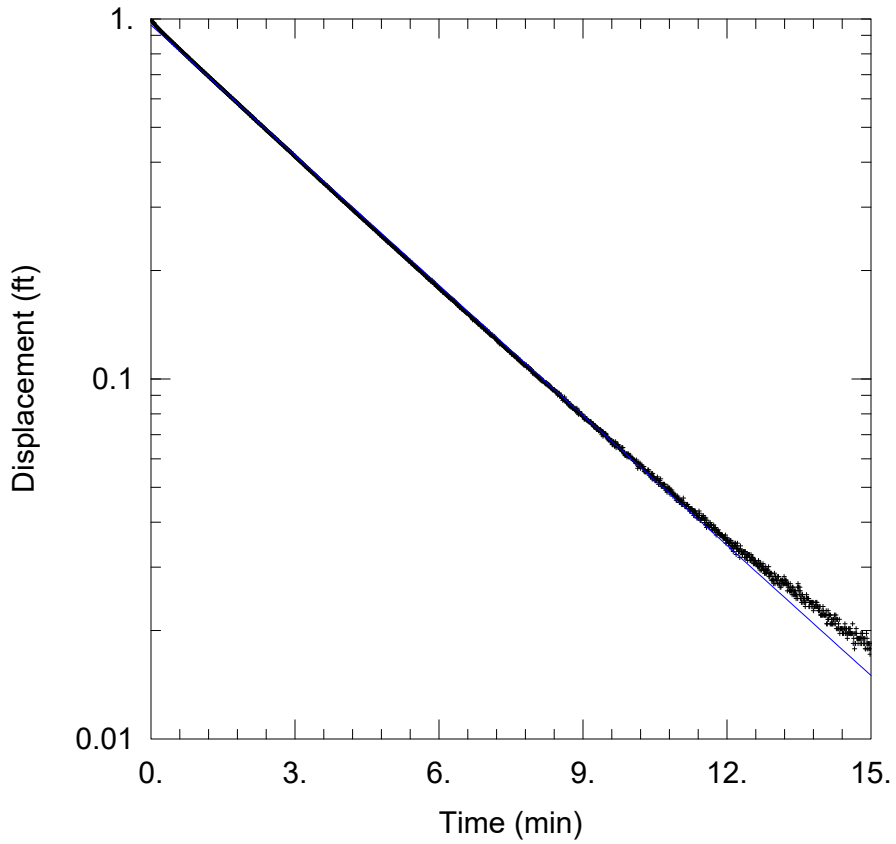
Saturated Thickness: 20.9 ft

Anisotropy Ratio (Kz/Kr): 0.1

WELL DATA (TW01)

Initial Displacement: 1. ft
Total Well Penetration Depth: 20.4 ft
Casing Radius: 0.1667 ft

Static Water Column Height: 20.9 ft
Screen Length: 10. ft
Well Radius: 0.333 ft



TW01 RH TEST 2

Data Set: Z:\...\TW01_RH-T2.aqt
Date: 09/26/19 Time: 11:18:00

PROJECT INFORMATION

Company: Stantec
Client: TVA-KIF
Project: 175668043
Location: Kingston Fossil Plant
Test Well: TW01
Test Date: 06/18/19

SOLUTION

Aquifer Model: Unconfined
Solution Method: Bouwer-Rice

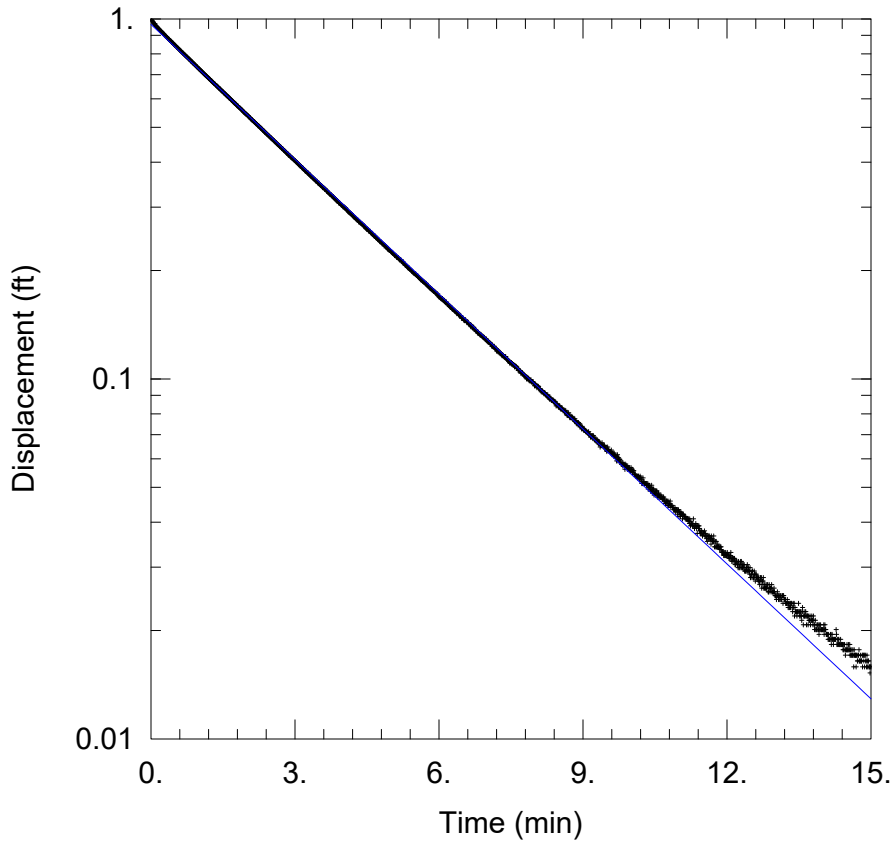
K = 2.089 ft/day
y0 = 0.9612 ft

AQUIFER DATA

Saturated Thickness: 20.9 ft
Anisotropy Ratio (Kz/Kr): 0.1

WELL DATA (TW01)

Initial Displacement: 1. ft
Total Well Penetration Depth: 20.4 ft
Casing Radius: 0.1667 ft
Static Water Column Height: 20.9 ft
Screen Length: 10. ft
Well Radius: 0.333 ft



TW01 RH TEST 3

Data Set: Z:\...\TW01_RH-T3.aqt
Date: 09/26/19 Time: 11:17:24

PROJECT INFORMATION

Company: Stantec
Client: TVA-KIF
Project: 175668043
Location: Kingston Fossil Plant
Test Well: TW01
Test Date: 06/18/19

SOLUTION

Aquifer Model: Unconfined
Solution Method: Bouwer-Rice

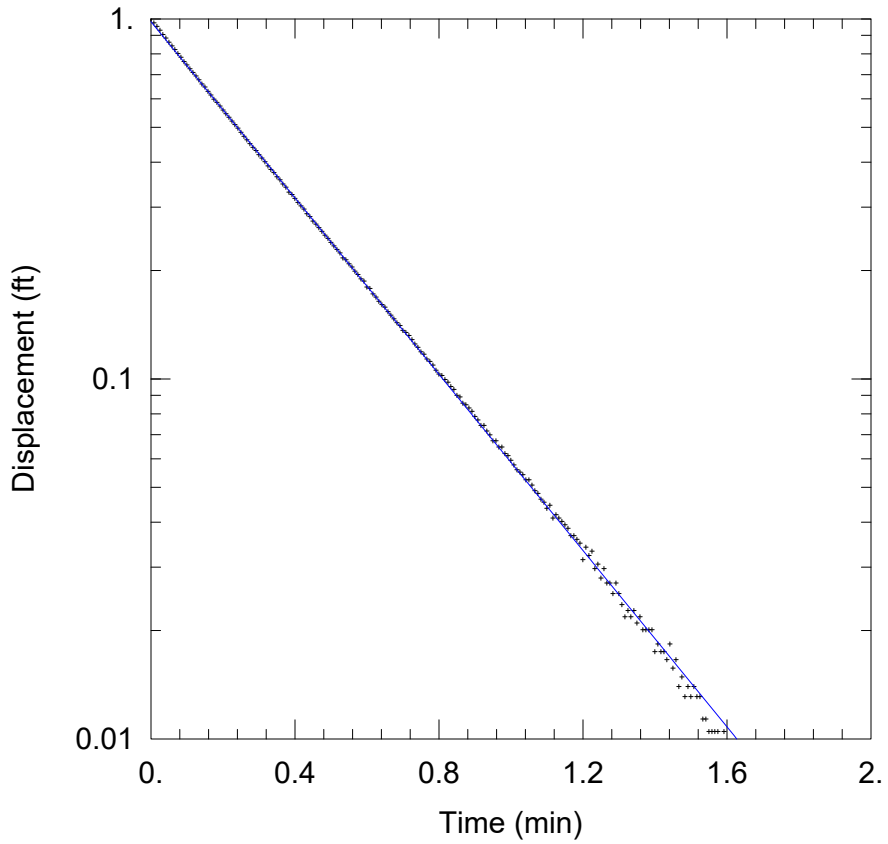
K = 2.166 ft/day
y0 = 0.9653 ft

AQUIFER DATA

Saturated Thickness: 20.9 ft
Anisotropy Ratio (Kz/Kr): 0.1

WELL DATA (TW01)

Initial Displacement: 1. ft
Total Well Penetration Depth: 20.4 ft
Casing Radius: 0.1667 ft
Static Water Column Height: 20.9 ft
Screen Length: 10. ft
Well Radius: 0.333 ft



TW02 FH TEST 1

Data Set: Z:\...\TW02_FH-T1.aqt
Date: 09/26/19 Time: 11:27:10

PROJECT INFORMATION

Company: Stantec
Client: TVA-KIF
Project: 175668043
Location: Kingston Fossil Plant
Test Well: TW02
Test Date: 06/19/19

SOLUTION

Aquifer Model: Unconfined
Solution Method: Bouwer-Rice

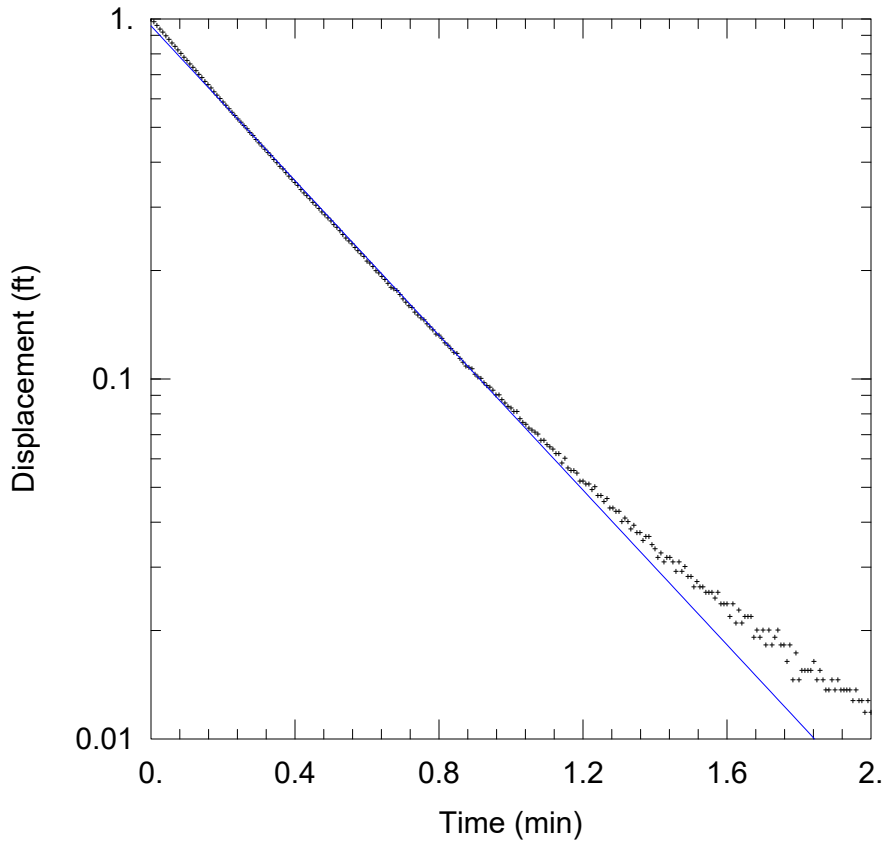
K = 21.82 ft/day
y0 = 0.9823 ft

AQUIFER DATA

Saturated Thickness: 23.9 ft
Anisotropy Ratio (Kz/Kr): 0.1

WELL DATA (TW02)

Initial Displacement: 1. ft
Total Well Penetration Depth: 23.5 ft
Casing Radius: 0.1667 ft
Static Water Column Height: 23.9 ft
Screen Length: 10. ft
Well Radius: 0.333 ft



TW02 FH TEST 2

Automatic Hammer Energy Verification Report

Stantec Consulting Services Inc.
3052 Beaumont Centre Circle, Lexington KY 40513-1703

March 7, 2021 175668043

Attention: Mr. Jeff Dingrando
Stantec Consulting Services Inc.
3052 Beaumont Centre Circle
Lexington, Kentucky 40513-1703

Reference: Automatic Hammer Energy Verification – CME 55 #1 (#709) Track Drill Rig SN: 330045

Dear Mr. Dingrando,

Stantec Consulting Services Inc. (Stantec) is pleased to submit this letter regarding the automatic Standard Penetration Test (SPT) hammer energy verification of your 2004 CME 55 Track #1 (#709) SN: 330045. Included within this letter is a summary table followed by a detailed description of the testing equipment used, testing procedures and a summary of the test results.

Summary of Automatic Hammer Energy Verification	
Rig ID:	Stantec CME 55 Track #1 (#709) SN: 330045
Hammer Type:	CME Automatic (140-lb)
Project and Location:	TVA KIF Seismic Borings, Kingston, Tennessee
Test Date and Time:	February 23, 2021 0800 - 1300
Equipment Operator:	Benjamin A. Halada (Stantec)
Drill Operator:	Eddie Caudill (Stantec)
Energy Transfer Ratio (%) [Low-High-**Average**]	84.2% - 95.6% - **89.8%**

Equipment and Procedures

SPT hammer energy verification was performed on Tuesday, February 23, 2021 in Kingston, Tennessee, while the drill was operating on the Tennessee Valley Authority (TVA) Kingston Fossil Plant property. Stantec utilized energy measurement equipment manufactured by Pile Dynamics, Inc. (PDI), of Cleveland, Ohio. Equipment for data acquisition for energy measurements for dynamic penetrometers (per ASTM D 4633) consisted of PDI's Pile Driving Analyzer, Model SPT (SN 4565 TB), an instrumented NW-J rod (SN 393NWJ) with two strain gages (SN 393NWJ-1 and 393NWJ-2) and two piezoresistive accelerometers (SN K3739 and K3740). This system has a sampling frequency of 50 kHz. The instrumented rod measured two-feet in length and was located at the top of the drill string during energy measurement. The strain gages and accelerometers were located one-foot below the top of the instrumented rod. The SPT's were driven per ASTM D 1586.

The above referenced drill rig is equipped with a Central Mine Equipment (CME) automatic SPT hammer that utilizes a hydraulic motor to turn a chain that in turn lifts a 140-lb drive weight and releases the weight for a free fall distance of 30 inches. The drive weight impacts

Reference: Automatic Hammer Energy Verification – CME 55 #1 (#709) Track Drill Rig SN: 330045

a CME anvil (12.75 inches in length and 2.50 inches in diameter) that is threaded into the top of the instrumented rod. During the energy measurements, the hammer was operated in accordance with the manufacturers recommendations, was not lubricated between or during standard penetration tests, the blow rate was approximately 54 blows per minute and the auto hammer / sample rods were kept vertical. At the time of the tests, the weather was 35 to 60° Fahrenheit with sunny skies and little to no wind.

Standard Penetration Testing was performed using a standard two-inch outer diameter split spoon sampler that was driven 1.5 feet. Testing began at a depth of 17.5 feet below the ground surface and was performed intermittently to 38.0 feet below the ground surface. The boring was advanced using a 4 7/8" diameter updraft bit and a bentonite based drilling fluid that had an average density of 9.0 lbs/gal. During the testing, the maximum transferred energy (EMX) was measured by the instrumented rod and compared to the theoretical potential energy (TPE) of the 140-lb drive weight dropping 30 inches. An energy transfer ratio (ETR) was then computed by dividing the EMX by the TPE.

Closing

The ETR for your 2004 CME 55 Track #1 (#709) SN: 330045 ranged from a low of 84.2% to a high of 95.6% with an average of 89.8%. Per ASTM D 4633, this hammer energy verification is valid for one year from the testing date of February 23, 2021. The attached Table 1 presents detailed results of the energy measurement.

Regards,

Pile Driving Analyzer, Model SPT Calibration

Certificate of Calibration

Pile Dynamics, Inc. certifies that the

Pile Driving Analyzer®, Model SPT

Serial Number: 4565 TB

was calibrated on 16 Oct 2020

using a PDA Calibration Box whose output was calibrated with test equipment traceable to NIST.

This certificate is valid for 2 years from above date.

Tested by: MO

Pile Dynamics, Inc.
30725 Aurora Road
Cleveland, Ohio 44139 USA

Certificate of Compliance

Pile Dynamics, Inc. certifies that the

Pile Driving Analyzer®, Model SPT

Serial Number: 4565 TB

has been tested and passed all final test procedures on 16 Oct 2023

SEAL

Tested by: MCO

1. The criterion for drained failure was considered to be the maximum effective principal stress ratio (maximum obliquity).

2. The criterion for undrained failure was considered to be the greater of the maximum deviator stress or the deviator stress at 15 percent axial strain.

Test Results

Natural Moisture Content

Test Method: ASTM D 2216

Moisture Content (%): 25.0

Particle Size Analysis

Preparation Method: ASTM D 421
Gradation Method: ASTM D 422
Hydrometer Method: ASTM D 422

Particle Size		%
Sieve Size	(mm)	Passing
	N/A	
	N/A	
	N/A	
1 1/2"	37.5	100.0
3/4"	19	93.7
3/8"	9.5	89.7
No. 4	4.75	87.4
No. 10	2	84.1
No. 40	0.425	79.4
No. 200	0.075	73.1
	0.02	61.5
	0.005	52.7
	0.002	46.8
estimated	0.001	42.5

Plus 3 in. material, not included: 0 (%)

	ASTM	AASHTO
Range	(%)	(%)
Gravel	12.6	15.9
Coarse Sand	3.3	4.7
Medium Sand	4.7	---
Fine Sand	6.3	6.3
Silt	20.4	26.3
Clay	52.7	46.8

Atterberg Limits

Test Method: ASTM D 4318 Method A
Prepared: Dry

Liquid Limit:	72
Plastic Limit:	25
Plasticity Index:	47
Activity Index:	1.0

Moisture-Density Relationship

Test Not Performed

Maximum Dry Density (lb/ft^3):	N/A
Maximum Dry Density (kg/m^3):	N/A
Optimum Moisture Content (%):	N/A
Over Size Correction %:	N/A

California Bearing Ratio

Test Not Performed

Bearing Ratio (%):	N/A
Compacted Dry Density (lb/ft^3):	N/A
Compacted Moisture Content (%):	N/A

Specific Gravity

Estimated

Particle Size:	No. 10
Specific Gravity at 20° Celsius:	2.70

Classification

Unified Group Symbol:	CH
Group Name:	Fat clay with sand
AASHTO Classification:	A-7-6 (35)

Consolidated Undrained Triaxial Compression

ASTM D 4767

Project Name	KIF TDEC Order	Project No.	175668043
Source	KIF-GT-TW04-ST02, 39.9'-40.5'	Lab ID	112
Description	Sandy Silt (ML), gray, wet, soft	Test ID	112-A
Specimen Type	Intact		
Preparation	Wet Mounting	Date Received	03/28/2019
		Date Tested	05/07/2019

Specific Gravity	2.43
ASTM D 854, Dry	
Liquid Limit	NP
Plastic Limit	NP
Plasticity Index	NP
ASTM D 4318	

Target Test Parameters

Nominal Chamber Pressure (psi)	90
Nominal Back Pressure (psi)	55
Nominal Consolidation Pressure (psi)	35

Saturation / Consolidation Results

Pore Pressure Parameter B	0.95
Measured Effective Consol. Stress (tsf)	2.501
Time to 50% Consolidation (min)	0.04
Actual Axial Strain Rate of Test (%/min)	0.100

Consolidated Specimen Conditions

Moist Unit Weight (pcf)	110.2
Moisture Content (%)	35.5
Dry Unit Weight (pcf)	81.3
Void Ratio	0.862
Degree of Saturation (%)	100.0

At Drained Failure

Failure Criterion: Max. Eff. Prin. Stress Ratio

Axial Strain (%)	4.856
Deviator Stress (tsf)	5.811
Induced Pore Pressure (tsf)	0.294
Minor Effective Stress, σ_3' (tsf)	2.213
Major Effective Stress, σ_1' (tsf)	8.024
Eff. Principal Stress Ratio, σ_1'/σ_3'	3.626
p' (tsf)	5.119
q (tsf)	2.906

At Consolidated Undrained Failure

Failure Criterion: Peak Deviator Stress

Axial Strain (%)	9.868
Deviator Stress (tsf)	8.863
Minor Principal Stress, σ_3 (tsf)	2.496
Major Principal Stress, σ_1 (tsf)	11.359
p (tsf)	6.928
q (tsf)	4.431

Consolidated Undrained Triaxial Compression

ASTM D 4767

Project Name KIF TDEC Order
Source KIF-GT-TW04-ST02, 39.9'-40.5'
Description Sandy Silt (ML), gray, wet, soft

Project No. 175668043
Lab ID 112
Test ID 112-A

Initial Specimen Conditions		Consolidated Specimen Conditions	
Average Height (in)	5.717	Calculated Height (in)	5.678
Average Diameter (in)	2.883	Calculated Diameter (in)	2.753
Calculated Area (in^2)	6.528	Calculated Area (in^2)	5.954
Moist Weight (lb)	2.228	Moist Weight (lb)	2.156
Moist Unit Weight (pcf)	103.1	Moist Unit Weight (pcf)	110.2
Moisture Content (%)	40.0	Moisture Content (%)	35.5
Dry Weight (lb)	1.591	Dry Weight (lb)	1.591
Dry Unit Weight (pcf)	73.7	Dry Unit Weight (pcf)	81.3
Void Ratio	1.055	Void Ratio	0.862
Degree of Saturation (%)	92.1	Degree of Saturation (%)	100.0

Specific Gravity 2.43
ASTM D 854, Dry

Liquid Limit NP
Plastic Limit NP
Plasticity Index NP
ASTM D 4318

Confining Stress
σ_3 (tsf) 2.512

Effective Consolidation Stress
σ_3' (tsf) 2.512

Moisture contents obtained using partial specimen.
Specimen consolidated cross-sectional area determined using method B.
Membrane corrections have been applied,where Em = 200 lbf/in and t = 0.012 in.
All other tests performed in association with this specimen are reported separately.

Stantec

Consolidated Undrained Triaxial Compression

ASTM D 4767

Project Name	TVA KIF EIP Exploratory Drilling	Project No.	175668043
Source	KIF-GT-TW05-ST01, 39.7'-40.2'	Lab ID	12
Description	Lean Clay with Sand (CL), light brown, moist, soft to firm	Test ID	12-A
Specimen Type	Intact		
Preparation	Wet Mounting	Date Received	12/03/2018
		Date Tested	12/04/2018

Specific Gravity	2.67
ASTM D 854, Dry	
Liquid Limit	26
Plastic Limit	17
Plasticity Index	9
ASTM D 4318	

Target Test Parameters

Nominal Chamber Pressure (psi)	90
Nominal Back Pressure (psi)	65
Nominal Consolidation Pressure (psi)	25

Saturation / Consolidation Results

Pore Pressure Parameter B	0.98
Measured Effective Consol. Stress (tsf)	1.484
Time to 50% Consolidation (min)	18.50
Actual Axial Strain Rate of Test (%/min)	0.016

Consolidated Specimen Conditions

Moist Unit Weight (pcf)	131.6
Moisture Content (%)	18.8
Dry Unit Weight (pcf)	110.8
Void Ratio	0.502
Degree of Saturation (%)	100.0

At Drained Failure

Failure Criterion: Max. Eff. Prin. Stress Ratio

Axial Strain (%)	5.543
Deviator Stress (tsf)	2.855
Induced Pore Pressure (tsf)	0.484
Minor Effective Stress, σ_3' (tsf)	1.008
Major Effective Stress, σ_1' (tsf)	3.863
Eff. Principal Stress Ratio, σ_1'/σ_3'	3.831
p' (tsf)	2.436
q (tsf)	1.427

At Consolidated Undrained Failure

Failure Criterion: 15% Axial Strain

Axial Strain (%)	15.067
Deviator Stress (tsf)	3.928
Minor Principal Stress, σ_3 (tsf)	1.455
Major Principal Stress, σ_1 (tsf)	5.383
p (tsf)	3.419
q (tsf)	1.964

Consolidated Undrained Triaxial Compression

ASTM D 4767

Project Name: TVA KIF EIP Exploratory Drilling
Source: KIF-GT-TW05-ST01, 39.7'-40.2'
Description: Lean Clay with Sand (CL), light brown, moist, soft to firm

Project No.: 175668043
Lab ID: 12
Test ID: 12-A

Initial Specimen Conditions		Consolidated Specimen Conditions	
Average Height (in)	5.826	Calculated Height (in)	5.808
Average Diameter (in)	2.883	Calculated Diameter (in)	2.788
Calculated Area (in^2)	6.529	Calculated Area (in^2)	6.105
Moist Weight (lb)	2.815	Moist Weight (lb)	2.700
Moist Unit Weight (pcf)	127.9	Moist Unit Weight (pcf)	131.6
Moisture Content (%)	23.9	Moisture Content (%)	18.8
Dry Weight (lb)	2.273	Dry Weight (lb)	2.273
Dry Unit Weight (pcf)	103.3	Dry Unit Weight (pcf)	110.8
Void Ratio	0.611	Void Ratio	0.502
Degree of Saturation (%)	104.2	Degree of Saturation (%)	100.0

Specific Gravity: 2.67
ASTM D 854, Dry

Liquid Limit: 26
Plastic Limit: 17
Plasticity Index: 9
ASTM D 4318

Confining Stress
σ_3 (tsf): 1.489

Effective Consolidation Stress
σ_3' (tsf): 1.489

Moisture contents obtained using partial specimen.
Specimen consolidated cross-sectional area determined using method B.
Membrane corrections have been applied,where Em = 200 lbf/in and t = 0.012 in.
All other tests performed in association with this specimen are reported separately.

Phase 1 Hydraulic Conductivity Testing Results

Hydraulic Conductivity of Saturated Porous Materials Using a Flexible Wall Permeameter

ASTM D 5084, Method C

Project Name	KIF TDEC Order			Project No.	175668043
Source	KIF-GT-TW01, ST02, 24.6'-24.9'			Test ID	27
Description	Silt (ML), gray, moist, firm			Prepared By	KG
		Specific Gravity	2.34 ASTM D854, Dry	Date	4-23-19
Specimen	Undisturbed	LL	NP		
Preparation	Trimmed in a trimming ring	PL	NP	Maximum Dry Density (pcf)	
Permeant	De-aired Tap Water	PI	NP	Percent of Maximum	

Specimens (if compacted) were compacted in a Proctor Mold as follows: The Maximum Dry Density was converted to Wet Density, this mass was divided by 4 (layers) and 3 of the 4 layers were compacted into the mold using a Proctor Hammer using 19 blows per layer. The density was varied by reducing the height of the drop by the amount listed beside "Compacted".

The specimen was trimmed from the bottom two layers.

	Initial Specimen Data	After Consolidation Data	After Test Data	Final Pressures (psi)			
Height (in.)	1.4579	1.4593	1.4517	Chamber	35		
Diameter (in.)	2.7975		2.7898	Influent	20.1		
Moisture Content (%)	31.5		31.6	Effluent	20	Applied Head Difference (psi)	0.1
Dry Unit Weight (pcf)	82.6		83.4			Back Pressure Saturated to (psi)	20
Void Ratio	0.769		0.752			Maximum Effective Consolidation Stress (psi)	15
Degree of Saturation (%)	95.7		98.2			Minimum Effective Consolidation Stress (psi)	14.9

						Hydraulic Conductivity			
Date	Clock (24H:M)	Temp. (°F)	Bottom Head (in)	Top Head (in)	Test Time (sec)	k (m/s)	k (cm/s)	k @ 20° C (m/s)	k @ 20° C (cm/s)

Hydraulic Conductivity of Saturated Porous Materials Using a Flexible Wall Permeameter

ASTM D 5084, Method C

Project Name	KIF TDEC Order			Project No.	175668043
Source	KIF-GT-TW02-ST01, 21.5'-21.8'			Test ID	50
Description	Silt (ML), gray, moist, firm			Prepared By	KG
		Specific Gravity	2.31 ASTM D854, Dry	Date	4-24-19
Specimen	Undisturbed	LL	NP		
Preparation	Trimmed in a trimming ring	PL	NP	Maximum Dry Density (pcf)	
Permeant	De-aired Tap Water	PI	NP	Percent of Maximum	

Specimens (if compacted) were compacted in a Proctor Mold as follows: The Maximum Dry Density was converted to Wet Density, this mass was divided by 4 (layers) and 3 of the 4 layers were compacted into the mold using a Proctor Hammer using 19 blows per layer. The density was varied by reducing the height of the drop by the amount listed beside "Compacted".

The specimen was trimmed from the bottom two layers.

	Initial Specimen Data	After Consolidation Data	After Test Data	Final Pressures (psi)			
Height (in.)	1.4579	1.4382	1.4356	Chamber	40		
Diameter (in.)	2.7975		2.8078	Influent	20.2		
Moisture Content (%)	34.3		32.1	Effluent	20	Applied Head Difference (psi)	0.2
Dry Unit Weight (pcf)	82.0		82.6			Back Pressure Saturated to (psi)	20
Void Ratio	0.759		0.745			Maximum Effective Consolidation Stress (psi)	20
Degree of Saturation (%)	104.4		99.4			Minimum Effective Consolidation Stress (psi)	19.8

						Hydraulic Conductivity

APPENDIX G – BATHYMETRIC SURVEY RESULTS

Exhibit No.

G.1

Title

Bathymetric Contour Map of the Intake Channel

Client/Project

Tennessee Valley Authority
Kingston Fossil Plant (KIF) TDEC Order

Project Location

Roane County, Tennessee

175668043

Prepared by DMB on 2022-01-06
Technical Review by JD on 2022-01-06

0 50 100 150 200 Feet

1:600 (At original document size of 22x34)

Legend

- Major Contour (Contour Interval = 5 ft)
- Minor Contour (Contour Interval = 1 ft)
- Edge of Water (December 3, 2020)
- CCR Unit Area (Approximate)
- Engineered Wetlands (Approximate)
- Polishing Pond (Approximate)

Notes

1. Coordinate System: NAD 1983 StatePlane Tennessee FIPS 4100 Feet
2. Imagery provided by TVA and flown by Tuck Mapping on March 16, 2017.
3. Bathymetric contours for the Intake Channel were provided by TVA and were surveyed on December 3, 2020 for project KIF202479 and Task Id: TTF685.

1.0 INTRODUCTION

Stantec Consulting Services Inc. (Stantec) has prepared this sampling and analysis report (SAR), on behalf of the Tennessee Valley Authority (TVA), to document activities related to the static stability analyses at TVA's Kingston Fossil (KIF) Plant located in Harriman, Tennessee (see Exhibit A.1 in Appendix A).

The purpose of the Static Stability SAR is to develop slope stability models, including material parameters, and perform slope stability analyses for the selected coal combustion residuals (CCR) units, in support of fulfilling the requirements for the Tennessee Department of Environment and Conservation (TDEC) issued Commissioner's Order No. OGC15-0177 (TDEC Order) to the TVA (TDEC 2015). The TDEC Order set forth a "process for the investigation, assessment, and remediation of unacceptable risks" at TVA's coal ash disposal sites in Tennessee.

The purpose of this Static Stability SAR is to summarize activities completed to meet the objectives of the Stability Sampling and Analysis Plan (SAP) (Stantec 2018a), for applicable static load cases. Seismic load cases (if any) required by the SAP are documented in a separate Seismic Stability SAR. This SAR presents results of static stability analyses (also referred to herein as stability analyses) and compares those results to acceptance criteria defined in the SAP. However, this SAR is not intended to provide conclusions of the stability analysis. The scope of the stability analysis activities represented herein was conducted pursuant to the SAP and is part of a larger environmental investigation at the KIF Plant. The evaluation of the results will consider other aspects of the environmental investigation, as well as data collected under other State and/or CCR programs and will be presented in the Environmental Assessment Report (EAR).

The Static Stability SAR activities were performed in general accordance with the following documents developed by TVA to support fulfilling the requirements of the TDEC Order:

- *Stability SAP* (Stantec 2018a)
- *Environmental Investigation Plan (EIP)* (Stantec 2018b)
- *Quality Assurance Project Plan (QAPP)* (Environmental Standards, Inc. 2018).

2.0 OBJECTIVE AND SCOPE

The primary objective of the Static Stability SAR, conducted pursuant to the Stability SAP, was to develop slope stability models, including material parameters, and perform static stability analyses for select CCR units at the KIF Plant, in response to the TDEC Order. The Stability SAP included slope stability models and static, global analyses at two cross sections at the Sluice Trench and Ballfield East of the Sluice Trench: Section A-A' and the "Polishing Pond" Section. Cross sections are presented in Section 4.2. The Stability SAP also included static, veneer stability analyses at typical cross sections at the Sluice Trench and Ballfield East of the Sluice Trench. The approach for the Static Stability SAR was to:

- Review historical and TDEC Order subsurface explorations of the site to characterize the subsurface conditions
- Review and compile historical and TDEC Order laboratory testing of materials to determine material properties
- Conduct the required global and veneer stability analyses for the various load cases.

The scope of work of the Static Stability SAR consisted of the following tasks:

- Develop material properties and strengths
- Model the subsurface conditions at each cross section, including the phreatic surface
- Conduct global stability analyses for the required load cases (long-term and drained)
- Conduct veneer stability analyses for the required load cases (long-term and drained)
- Compare results against the acceptance criteria defined in the SAP; for cases (if any) not meeting the acceptance criteria, further assessment will be appropriate per the phased approach defined in the Stability SAP.

Table 1 provides the stability analyses (i.e., load cases) conducted for each CCR unit. In cases where new analyses were not performed, existing analyses adequately address the load case(s) for the unit.

Table 1. Stability Analyses Completed for each CCR Unit

CCR[1] Unit and Condition	Static Cases	
	Long-Term, Global	Long-Term, Veneer[2]
Interim Ash Staging Area (Closed Condition)	–[3]	–[3]
Sluice Trench and Ballfield East of Sluice Trench (Closed Condition)	X	X
Stilling Pond (Closed Condition)	–[4]	–[4]

Notes:

1. CCR = coal combustion residuals
2. Veneer stability is the slope stability of the final cover
3. Stability calculations are not required to demonstrate performance of the closed conditions due to the higher surrounding grade, flat closure grading, and containment towards the east by the Polishing Pond
4. The reassessment of the Stilling Pond closure design includes analyses sufficient to address the necessary load cases.

Details of the analyses performed are presented in the sections below. Graphical stability analysis results are included in Appendix B (global stability) and Appendix C (veneer stability). Supplemental information for characterizing soil parameters are included in Appendix D.

3.0 PHYSICAL SETTING AND SITE HISTORY

3.1 EXISTING CONDITIONS

The Sluice Trench and Ballfield East of Sluice Trench (Figure 1) was capped and closed in 2019. The unit is located along the Emory River, near the intake for the plant. The unit includes a clay embankment dike known as the East Dike, the water quality channel, and a portion of the Polishing Pond. The East Dike forms the southeastern perimeter of the unit. The Engineered Wetlands area is outside the limits of the CCR unit. With respect to the stability of this CCR unit, the focus is on slope failures along the East Dike that could result in a release of CCR to the adjacent river/intake channel.

Figure 1. Sluice Trench and Ballfield East of Sluice Trench, showing East Dike Location

3.2 GEOLOGIC SETTING

The plant is situated on the western edge of the Valley and Ridge Physiographic province near the base of the Cumberland Plateau. Numerous faults, trending northeast to southwest as characteristic of the Valley and Ridge Province, are depicted on the geologic mapping. The plant is positioned between the Chattanooga Fault to the north, and the Kingston Fault to the south.

According to the United States Geological Survey Geologic Map of the Harriman Quadrangle (Moore, Finlayson, and Milici 1993), the plant is underlain by Lower Ordovician and Cambrian age limestone and shale bedrock formations. Although not depicted on the geologic mapping, previous drilling programs at the plant indicate that alluvial deposits consisting of fine sands, silty sands, and sandy silts are present at the site, as are commonly found adjacent to rivers.

The majority of the plant, including the Sluice Trench and Ballfield East of Sluice Trench, is underlain by the Conasauga Shale Formation, which consists of an argillaceous to silty shale with zones of shaley limestone scattered throughout. The geologic mapping indicates this formation is contorted, brecciated, and sheared throughout. The geologic mapping indicates Pine Ridge, just north of the plant, and the northern corner of the Kingston Recovery Project (KRP) Ash Landfill are underlain by the Rome Formation, consisting of arenaceous shale interbedded with very thin siltstone layers and thin beds of sandstone.

3.3 SITE HISTORY

TVA constructed the KIF Plant from 1951 to 1954 and commenced operations in 1954. In 1956, the East Dike was constructed as part of the initial ash disposal area, which includes the footprints of the present-day Sluice Trench and Ballfield East of Sluice Trench and the Interim Ash Staging Area. Construction of the perimeter containment dikes around the former main ash pond were completed in 1958.

The sluice trench was constructed in the late 1960s along the east portion of the initial ash disposal area. The sluice trench was used to sluice ash from the plant to the former main ash pond, which is now within the footprint of the KRP Ash Landfill (Calvert 1967 and 1968). Historical annual inspections (Parrish 1970) reported that the ash was generally sluiced quickly enough from the plant to the main ash pond such that there was minimal ash deposition in the sluice trench.

As part of the KRP, CCR was temporarily staged at the Sluice Trench and the Interim Ash Staging Area. The staged ash was removed in 2015, and as part of the closure a low permeability soil cap was constructed. The closure design of the Interim Ash Staging Area (AECOM 2016a, 2016b, and 2016c) generally leveled the site to conform to the higher surrounding grades, with gentle slopes (3 percent [%] maximum) and small perimeter ditches to promote surface drainage.

In 2015, as part of the cap construction for the Sluice Trench unit, the Sluice Trench was filled in and a new Water Quality Channel was constructed to the southeast along a parallel alignment. The Water Quality Channel was lined with a geomembrane and designed to convey process water to the Stilling Pond (TVA 2015). During the subsequent Polishing Pond construction, the Water Quality Channel was rerouted to convey the process water to the Polishing Pond.

The Polishing Pond was constructed in 2017 over a segment of the former Sluice Trench and a portion of the Ballfield East of Sluice Trench. The area was partially excavated and geosynthetic clay liner and a geomembrane were placed over the area within the limits of the Polishing Pond. Outside the limits of the Polishing Pond, a soil cap was constructed over another segment of the former Sluice Trench and another portion of the Ballfield East of Sluice Trench (AECOM 2016b).

CCR excavated during the closure of the Interim Ash Staging Area, Sluice Trench, and construction of the water quality channel and Polishing Pond was placed in the KRP Ash Landfill.

In 2018, a reverse graded filter and seepage collection system was constructed along the outboard face of the East Dike, as part of a seepage mitigation project (AECOM 2018). The filter and collection system were constructed to mitigate concerns from historical seeps observed along the outboard face of the dike.

In 2019, the last remaining uncapped portion of the Ballfield East of Sluice Trench was regraded and capped with a geomembrane and vegetative soil layer. As part of the regrading effort for the area, a heterogenous mix of CCR and soil was placed as structural fill to prepare the subgrade prior to constructing the cover system. This East Dike Area Closure project (AECOM 2019) capped the corridor between the East Dike and the areas that were already capped as part of the Water Quality Channel and Polishing Pond projects.

3.4 PRIOR SUBSURFACE INVESTIGATIONS

Historical boring and geotechnical data was used to supplement data collected during execution of the Exploratory Drilling (Phase 1 only), Hydrogeological Investigation, and Background Soil SAPs.

The prior subsurface investigations used to support the stability analysis of the Sluice Trench and Ballfield East of Sluice Trench include:

- Stantec (2009) – historical boring logs within the Engineered Wetlands adjacent to the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of the foundation soil subunits
- MACTEC (2009) – historical boring logs and laboratory testing from borings along the East Dike at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of the CCR and foundation soil subunits
- Geosyntec (2010a) – historical boring logs and laboratory testing from borings along the East Dike at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of the CCR, embankment dike material, and foundation soil subunits. Data from piezometers installed in these borings were used to develop phreatic surfaces for stability analyses.
- Geosyntec (2010b) – historical boring logs and laboratory testing from borings along the East Dike at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of the foundation soil subunits

- Geosyntec (2012) – historical boring logs and laboratory testing from borings along the East Dike at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of the CCR, embankment dike material, and foundation soil subunits
- AECOM (2016a) – historical boring logs and laboratory testing of soils from borings at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of CCR, embankment dike material, and foundation soil subunits
- AECOM (2016b) – historical boring logs, laboratory testing of soils from borings, and cone penetration test (CPT) soundings at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of CCR, embankment dike material, and foundation soil subunits
- Stantec (2017) – historical boring logs and laboratory testing were used to characterize the strengths and index properties of the foundation soil subunits.

3.5 PRIOR STABILITY ANALYSES

Prior stability analyses, which were reviewed when developing/updating stability models, for the Sluice Trench and Ballfield East of Sluice Trench include the following:

- Geosyntec (2010a): Static long-term global slope stability analysis of the East Dike
- Geosyntec (2010b): Static long-term and seismic (pseudostatic) short-term global slope stability analyses of the East Dike
- Geosyntec (2012): Static long-term global slope stability analysis of the East Dike, incorporating results of additional geotechnical exploration
- AECOM (2016b): Static long-term and seismic (pseudostatic and post-earthquake) short-term global stability analyses of the East Dike and Polishing Pond, incorporating results of additional geotechnical exploration.

The historical analyses of the Drainage and Flow Management Project (i.e., Polishing Pond and Water Quality Channel) constructed within the Sluice Trench and Ballfield East of Sluice Trench unit (AECOM 2016a, 2016b) do not include veneer stability analyses for long-term, drained conditions. Further, these available analyses did not include geometry changes from recent construction of a graded filter and seepage collection system along the outboard slope of the East Dike (AECOM 2017). Therefore, new static (global and veneer) analyses for the existing (with graded filter) conditions were performed. These analyses were performed in accordance with the Stability SAP.

4.0 SUBSURFACE CHARACTERIZATION

4.1 MATERIAL PROPERTIES

Subsurface materials are identified based on the project records, subsurface explorations, laboratory testing, and other available information. A material is a region or zone in the analytical model comprised of an idealized grouping of soil or rock sublayers of similar geologic origin or geotechnical behavior, subject to practical considerations in the analysis. A material is not necessarily a single type of soil or rock and may include significant variability. Field information may identify sub-layers or sub-units within a given material. The key materials (i.e., idealized groupings for characterization) for purposes of seepage and/or stability analyses are represented in Table 2, with the CCR units where the material is located and a brief description. Material delineation/zonation considered the potential for weak or otherwise distinct strata that may affect the static stability analyses. Such strata were modeled as separate materials, if/when appropriate. Physical properties of these materials are described in the subsections below. For context, the selected material parameters are compared to those used in historical analyses (where available, and for information only). For the shale bedrock, relevant material properties are described separately in subsection 4.1.4.

Table 2. Identification of Subsurface Materials at KIF Plant

Material Name	CCR Units	Description
Embankment Fill	Sluice Trench and Ballfield East of Sluice Trench	Compacted clay fill including the starter dike
Fly Ash	Sluice Trench and Ballfield East of Sluice Trench	Fly ash sluiced into the initial ash storage area
Bottom Ash	Sluice Trench and Ballfield East of Sluice Trench	Bottom ash sluiced (early operations) or placed and compacted (later operations); sometimes used as structural fill
Cover Material	Sluice Trench and Ballfield East of Sluice Trench	Compacted soil fill at the surface of the capped portions of the unit
Filter Materials	Sluice Trench and Ballfield East of Sluice Trench	American Society for Testing and Materials (ASTM) C33 concrete sand and Tennessee Department of Transportation (TDOT) No. 78 stone; part of 2018 reverse graded filter on East Dike outboard slope
Riprap	Sluice Trench and Ballfield East of Sluice Trench	TDOT A1 Riprap; part of 2018 reverse graded filter on East Dike outboard slope
Foundation Soil - Subunit 1 (Subunit 1)	Sluice Trench and Ballfield East of Sluice Trench	Natural, alluvial deposits of lean clay to silty lean clay soil
Foundation Soil - Subunit 2 (Subunit 2)	Sluice Trench and Ballfield East of Sluice Trench	Natural, alluvial deposits of silty sand to sandy silt, with no less than about 30% fines
Foundation Soil - Subunit 3 (Subunit 3)	Sluice Trench and Ballfield East of Sluice Trench	Natural, alluvial deposits of sand to silty sand, with less than about 30% fines
Shale[1]	Sluice Trench and Ballfield East of Sluice Trench	Weathered shale bedrock, with dipping beds and occasional layers of limestone

Notes:
1. For the shale bedrock, relevant material properties are described separately in subsection 4.1.4.

4.1.1 General Description and Geologic Origin

4.1.1.1 Embankment Fill

The Embankment Fill is generally described as a silty clay material with some shale fragments, as encountered during historical exploration. The Embankment Fill material was placed during the original construction of the East Dike at the perimeter of the initial ash disposal area, along the KIF Plant intake channel. Record drawings specify that the material should “be fine and relatively impervious,” and that “select firm shale material be placed below the water level” for a portion of the East Dike (TVA 1956). The Embankment Fill extends up to 29 feet (ft) in thickness along the crest of the original alignment of the East Dike.

In previous stability analyses (Geosyntec 2010a, 2012) the Embankment Fill was modeled as two zones, an upper and lower dike fill. The delineation of the zones correlates to a decrease in the Standard Penetration Test blowcounts (i.e., N-values). The delineation of the Embankment Fill was reevaluated as part of this study. The higher blowcounts were attributed to suction-induced strength above the phreatic surface. Otherwise, the upper and lower dike fill materials were similar in type and behavior. Therefore, the material was modeled as one material rather than two.

4.1.1.2 Fly Ash

The Fly Ash material is composed primarily of fine-grained CCR that is generally described as a non-plastic, sandy silt. The Fly Ash was sluiced into the initial ash disposal area, during early operations of the plant. The thickness ranges from four ft adjacent to the Embankment Fill to 15 ft in the interior of the Ballfield East of Sluice Trench.

4.1.1.3 Bottom Ash

The Bottom Ash material is composed primarily of coarse-grained CCR that is generally described as a silty sand to sandy silt. The Bottom Ash was placed during operation of the sluice trench in the Ballfield East of Sluice Trench, over the Fly Ash material. Some bottom ash was sluiced, while some was placed and compacted. Bottom Ash was sometimes used as structural fill, such as in the Polishing Pond perimeter dike. In some instances, bottom ash used as structural fill may contain some fraction of random soil fill. The Bottom Ash extends up to 35 ft thick in the interior of the Ballfield East of Sluice Trench.

4.1.1.4 Cover Material

The Cover Material was placed during the closure of the Sluice Trench and Ballfield East of Sluice Trench as part of the engineered soil cap. The soil was sourced from the “I-40 borrow area”, as detailed in the construction certification report for the closure of the unit (AECOM 2019). Per the closure documentation (AECOM 2019), the cap system consists of 24 inches of protective cover soil, overlying a geocomposite drainage layer (geotextile/geonet/geotextile) and geomembrane (textured 60-mil Linear Low-Density Polyethylene (LLDPE), overlying the CCR material. The geosynthetics were characterized using the typical properties from their respective manufacture product sheets (AGRU 2018 and SKAPS 2017) because no project-specific testing was available.

4.1.1.5 Filter Materials

The Filter Materials include ASTM C33 sand and TDOT No. 78 stone used in the reverse-graded filter constructed as part of the Seepage and Drainage repair along the East Dike (AECOM 2017). In this analysis, it was adequate to model the ASTM C33 sand and TDOT No. 78 stone as one material. The Filter Materials were sourced from the Rogers Roane County Quarry in Harriman, Tennessee (AECOM 2018). The thickness of the Filter Materials varies from two ft up to 3.5 ft along the outboard face of the East Dike.

4.1.1.6 Riprap

The Riprap consists of TDOT A1 Riprap placed as part of the Seepage and Drainage repair along the East Dike (AECOM 2017). The Riprap was sourced from the Rogers Roane County Quarry in Harriman, Tennessee (AECOM 2018). The Riprap was placed in a two-ft-thick layer over the Filter Materials along the outboard face of the East Dike.

4.1.1.7 Foundation Soils

The foundation soils underlying the site were generally more fine-grained, and plastic near the original ground surface and transitioned to a sandier, non-plastic material at greater depths, until bedrock was encountered. The transition between the materials was gradual and, although distinct horizon delineations were not noted, the foundation was divided into three subunits using the criteria listed in the subsections below. The varying presence of the uppermost foundation soil (Subunit 1) has been attributed to the alluvial deposition of the foundation soils.

4.1.1.7.1 Subunit 1

Subunit 1 is generally described as an alluvial, silty, lean clay deposit that comprises the upper portions of the alluvial foundation along the Emory River and intake channel, extending into the interior of the Sluice Trench and Ballfield East of Sluice Trench. Based on historical and TDEC Order borings, the presence and thickness of this subunit is highly variable across the site. Subunit 1 was not encountered in the vicinity of the Polishing Pond but was encountered under the East Dike closer to the intake channel. Where encountered, the thickness of Subunit 1 varies between approximately five ft at the interior of the Ballfield East of Sluice Trench and approximately 10 ft extending into the intake channel.

4.1.1.7.2 Subunit 2

Subunit 2 is generally described as a sandy silt to silty sand with no less than about 30% fines, comprising part of the alluvial foundation at the Sluice Trench and Ballfield East of Sluice Trench. Subunit 2 is continuous across the unit footprint and underlies Subunit 1 (where present). Where Subunit 1 is not present (e.g., the Polishing Pond), Subunit 2 is the uppermost foundation material. Subunit 2 varies in thickness from approximately five to 15 ft.

4.1.1.7.3 Subunit 3

Subunit 3 is generally described as an alluvial silty sand with less than about 30% fines and comprises the lower foundation. This subunit overlies the shale bedrock and varies in thickness from approximately five to 10 ft.

4.1.2 Index Properties, Classification, and Density Parameters

The stability analyses require unit weights (densities) for each material or zone that is modeled. Unit weights for each material are summarized in Table 3. These parameters were derived from available laboratory testing results using the methodology outlined in Appendix D.

Table 3. Density Parameters of the Subsurface Materials at KIF Plant

Material Name	G_s	w (%)	e	γ_d (pcf)	γ_m (pcf)	γ_{sat} (pcf)
Embankment Fill	2.70	23	0.61	104	128	128
Fly Ash	2.51	40	0.96	80	112	112
Bottom Ash	2.67	21	0.68	99	119	124
Cover Material	2.72	30	0.83	92	120	121
Filter Materials	2.77	20	0.65	105	126	130
Riprap	2.65	15	0.65	100	115	125
Subunit 1	2.69	24	0.63	103	127	127
Subunit 2	2.68	21	0.62	103	126	127
Subunit 3	2.74	20	0.56	110	131	132

Notes:

G_s	Specific Gravity of the solids	γ_d	dry unit weight
w	natural, gravimetric water content	γ_m	moist unit weight
e	void ratio	γ_{sat}	saturated unit weight
%	percent	pcf	pounds per cubic foot

The following subsections detail the available data and basis for selecting the density parameters for each material.

4.1.2.1 Embankment Fill

Historical index testing (AECOM 2016b, Geosyntec 2010a and 2010b) is available to characterize the Embankment Fill.

The aggregated historical laboratory testing of the Embankment Fill material produced an average moist unit weight of 128 pounds per cubic foot (pcf) which was selected as the representative moist unit weight for the material. A dry unit weight of 104 pcf was calculated based on the average moist unit weight and moisture content values. The Embankment Fill generally classified per ASTM D2487: *Standard Practice for Classification of Soils for Engineering Purposes (Unified Soil Classification System)* (USCS) as a sandy, lean clay (CL). The averages of the historical laboratory testing results were also used as the

representative void ratio and specific gravity values (0.61 and 2.70, respectively). The median fines content and average moisture content of the Embankment Fill material were 52%and 23%, respectively. The median fines content was selected due to outliers skewing the average fines content of the material.

The selected values are within the expected range for the material. See Appendix D for additional discussion of typical values. The values are also similar to those used in previous analyses. The supplemental assessment by Geosyntec (2012) used moist unit weights of 125 and 120 pcf for the Upper Dike Fill and Lower Dike Fill, respectively. The unit weight used in the historical analysis by AECOM (2016b) is 132 pcf, for their “Fill: Sandy Silt”, which is analogous to the Embankment Fill.

4.1.2.2 Fly Ash

The Fly Ash material was characterized using data from the Exploratory Drilling SAR and historical index testing (Geosyntec 2010a and 2010b, AECOM 2016b, and MACTEC 2009). Generally, average values from the recent and historical laboratory data were selected for use in the analyses. The Fly Ash material generally classified per USCS as a non-plastic, sandy silt (ML) and had an average fines content of 57 percent and average moisture content of 40%.

The average moist unit weight was 112 pcf. A dry unit weight of 80 pcf was calculated based on the average moist unit weight and moisture content values. The average void ratio and specific gravity from current and historical laboratory testing were also selected as the representative values (0.96 and 2.51, respectively).

The total unit weight for the Fly Ash is similar to the unit weight used in the latest stability from the Polishing Pond Report (AECOM 2016b) of 117 pcf. The Polishing Pond Report modeled the Fly Ash and Bottom Ash as a single material, Ash Fill. The average of the Fly Ash and Bottom Ash unit weights selected for this analysis is equal to the value used for the Ash Fill in the Polishing Pond assessment (AECOM 2016b). The Seepage and Stability Study for the East Dike (Geosyntec 2010a) and Supplemental Assessment of Seepage and Slope Stability (Geosyntec 2012) used a total unit weight of 75 pcf based on recommended values from previous analyses completed at the KIF Plant.

4.1.2.3 Bottom Ash

The Bottom Ash material was characterized using data from the Exploratory Drilling SAR and historical index testing (Geosyntec 2010a and 2010b, AECOM 2016b, and MACTEC 2009). Generally, average values from the recent and historical laboratory data were selected for use in the analyses. The Bottom Ash material generally classified per USCS as a silty sand (SM) to sandy silt (ML) and had an average fines content of 32% and average moisture content of 21%. The average moist unit weight was 119 pcf. The representative dry unit weight (99 pcf) was calculated based on the selected moist unit weight and moisture content values. The selected void ratio and specific gravity values for the Bottom Ash were also based on averages from laboratory data (0.68 and 2.67, respectively).

The selected moist unit weight for the Bottom Ash material is similar to the value (117 pcf) used for the “Ash Fill” materials in the Polishing Pond Engineering Report (AECOM 2016b). The Bottom Ash and Fly Ash were modeled as one material (Ash Fill) by AECOM. If the unit weights assigned herein to the Bottom

Ash and the Fly Ash are averaged, the result is equivalent to the unit weight of the previous Ash Fill. Other historical analyses assumed a lower value (100 pcf) based on limited data.

4.1.2.4 Cover Material

The Cover Material is generally classified as a fat clay with sand and was sourced from a borrow area offsite (I-40, Exit 364). Selected parameters for the Cover Material are based on the construction closure record document (AECOM 2019) for the Sluice Trench and Ballfield East of Sluice Trench. The moist unit weight selected was the average from seven proctor tests performed on seven bulk samples from the borrow site. The void ratio and moisture content were selected based on typical values (Appendix D).

4.1.2.5 Filter Materials

The Filter Materials include ASTM C33 sand and TDOT No. 78 stone (AECOM 2017) used to construct the reverse-graded filter along the East Dike. Properties for the Filter Materials in Table 3 were estimated using typical values.

4.1.2.6 Riprap

The Riprap consists of TDOT A1 Riprap (AECOM 2017). Properties for the Riprap in Table 3 were estimated using typical values.

4.1.2.7 Subunit 1

The Subunit 1 material is comprised of alluvial, plastic, fine-grained soil that classifies per USCS laboratory testing as lean clay (CL). The soil was characterized using data from the Exploratory Drilling SAR and historical index testing (Geosyntec 2010a and 2010b). Generally, average values from the recent and historical laboratory data were selected for use in the analyses. The Subunit 1 material had an average fines content of 79 percent and average moisture content of 24%.

The average moist unit weight was 127 pcf. The selected dry unit weight (103 pcf) was calculated using the selected moist unit weight and moisture content values. From the current and historical laboratory testing, the average void ratio and specific gravity were also selected as the representative values (0.63 and 2.69, respectively).

The moist unit weight for Subunit 1 is similar to that used in historical analyses. The Seepage and Stability Study for the East Dike (Geosyntec 2010a) and Supplemental Assessment of Seepage and Slope Stability (Geosyntec 2012) used a value of 125 pcf. The Polishing Pond Analysis, which modeled the foundation soil as a single unit, used a value of 117 pcf (AECOM 2016b). The selected moist unit weight for Subunit 1 is also similar to the value (125 pcf) used in the Stilling Pond Analysis (Stantec 2020).

4.1.2.8 Subunit 2

Subunit 2 consists of alluvial deposits classified per USCS laboratory testing as silty sand (SM) to sandy silt (ML) with fines content no less than about 30 percent. Historical index testing (Geosyntec 2010a and 2010b, MACTEC 2009, and AECOM 2016b) from various analyses and subsurface explorations was

used to characterize the soil. The Subunit 2 material had an average fines content of 47% and average moisture content of 21%.

The average moist unit weight was 126 pcf. The selected dry unit weight (103 pcf) was calculated using the selected moist unit weight and moisture content values. The average void ratio and specific gravity from historical laboratory testing were selected as the representative values (0.62 and 2.68, respectively).

The moist unit weight for Subunit 2 is similar to the unit weights used in historical stability analyses. The Seepage and Stability Study for the East Dike (Geosyntec 2010a) and Supplemental Assessment of Seepage and Slope Stability (Geosyntec 2012) used a value of 125 pcf. The Polishing Pond Analysis, which modeled the foundation soil as a single unit, used a value of 117 pcf (AECOM 2016b). The moist unit weight assigned to Subunit 2 is similar to the value (125 pcf) used in the KIF Plant Stilling Pond Stability Analysis (Stantec 2020).

4.1.2.9 Subunit 3

Subunit 3 consists of alluvial deposits classified per USCS laboratory testing as silty sand (SM) to sandy silt (ML) with fines content of less than about 30 percent. Historical index testing (Geosyntec 2010a and 2010b, AECOM 2016b) from various analyses and subsurface explorations was used to characterize the soil. The Subunit 3 material had an average fines content of 28% and average moisture content of 20%.

The average moist unit weight was 131 pcf. The selected dry unit weight (110 pcf) was calculated using the selected moist unit weight and moisture content values. The average void ratio and specific gravity from historical laboratory testing were selected as the representative values (0.56 and 2.74, respectively).

The selected moist unit weight for Subunit 3 is higher than the unit weights used in historical stability analyses. The Seepage and Stability Study for the East Dike (Geosyntec 2010a) and Supplemental Assessment of Seepage and Slope Stability (Geosyntec 2012) used a value of 120 pcf. The Polishing Pond Analysis, which modeled the foundation soil as a single unit, used a value of 117 pcf (AECOM 2016b). The moist unit weight assigned to Subunit 3 for the KIF Plant Stilling Pond Stability Analysis is 127 pcf (Stantec 2020).

4.1.3 Drained Strengths for Static, Long-term Conditions

Drained strength (effective stress) parameters, defined in terms of drained friction angle (φ') and drained cohesion (c'), for the subsurface materials under static, long-term conditions are summarized in Table 4. Determination of these parameters for each material is described in the subsections below. Background information, typical values, correlations, and measurement methods for characterizing the drained shear strength of soils are discussed in Appendix D. See Section 6.1.8 for discussion on how the drained strengths are applied in the stability model.

Table 4. Drained Shear Strength Parameters for the Analysis of Static, Long-term Conditions, for the Subsurface Materials at KIF Plant

Material Name	ϕ' (deg)	c' (tsf)
Embankment Fill	36	0
Fly Ash	34	0
Bottom Ash	37	0
Cover Material[1]	19	0
Filter Materials	33	0
Riprap	40	0
Subunit 1	32	0
Subunit 2	35	0
Subunit 3	37	0

Notes:

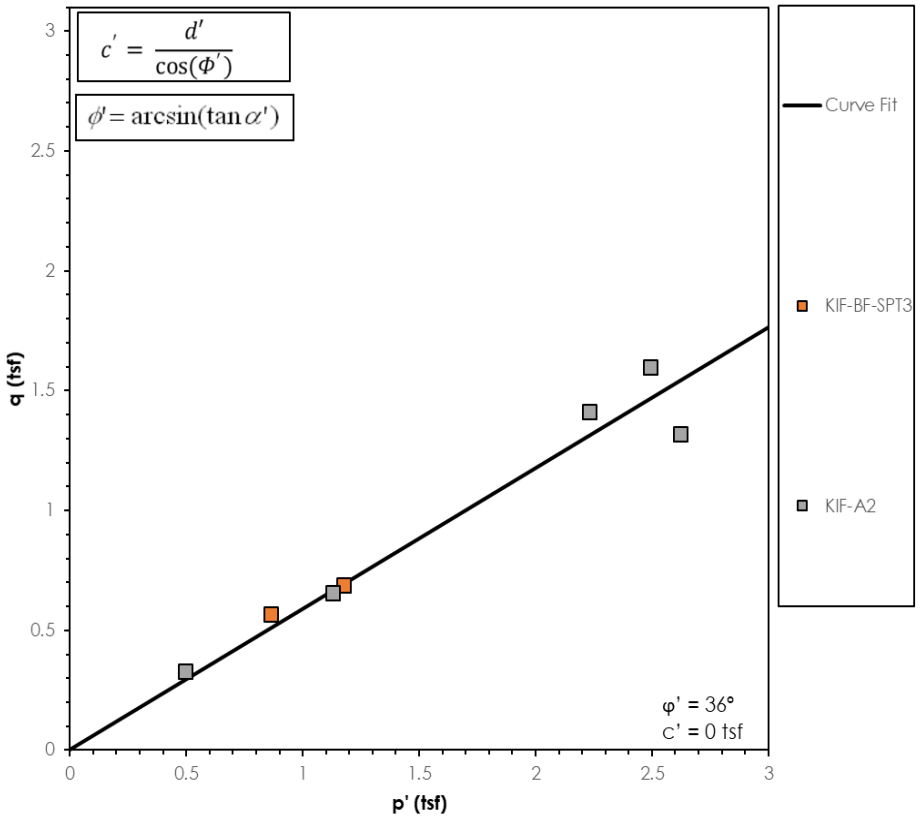
ϕ'	drained friction angle	c'	drained cohesion
deg	degrees	tsf	tons per square foot

1. To account for possible sliding along the geosynthetic interface within the cap system the cover system strength was assumed to be (φ' = 16° and c' = 0) in the global stability analyses.

4.1.3.1 Embankment Fill

Drained strength (effective stress) parameters for the Embankment Fill under static, long-term conditions are presented on Figure 2. Determination of these parameters is described below.

Figure 2. Drained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Embankment Fill



The selected strength envelope (c' = 0 tons per square foot (tsf) and φ' = 36º) is plotted with the isotropically consolidated undrained (CU) triaxial compression data from tests performed on undisturbed samples of the Embankment Fill as part of historical investigations (Geosyntec 2010a and AECOM 2016b). The data was obtained using maximum effective principal stress ratio as the failure criterion. The labels on Figure 2 indicate from which boring the samples were obtained.

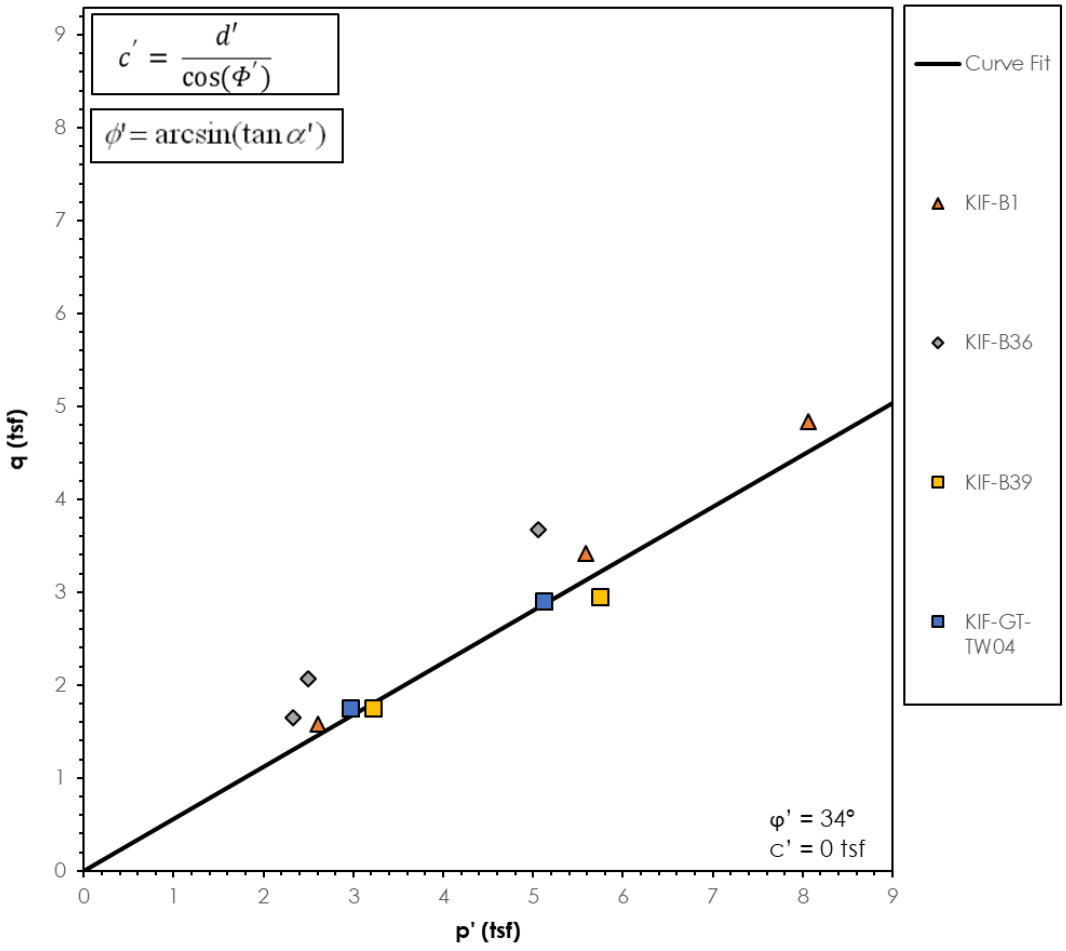
In total, data is available from seven CU triaxial tests. Overall, the data generally plots along a linear trend. The assigned strength parameters were selected by fitting the CU data per the two-thirds best fit rule (Appendix D).

The selected strength parameters (c' = 0 tsf and φ' = 36º) compare well to strengths used in historical analyses. The Supplemental Stability Assessment of the Slope Stability of the East Dike used CPT correlations estimate a friction angle range of 33 to 41 degrees, while conservatively using a 32-degree friction angle in the analysis (Geosyntec 2012). The Polishing Pond stability analysis similarly used a friction angle of 32 degrees based on CU triaxial data collected during the geotechnical exploration of the area (AECOM 2016a).

4.1.3.2 Fly Ash

Drained strength (effective stress) parameters for the Fly Ash under static, long-term conditions are presented on Figure 3. Determination of these parameters is described below.

Figure 3. Drained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Fly Ash



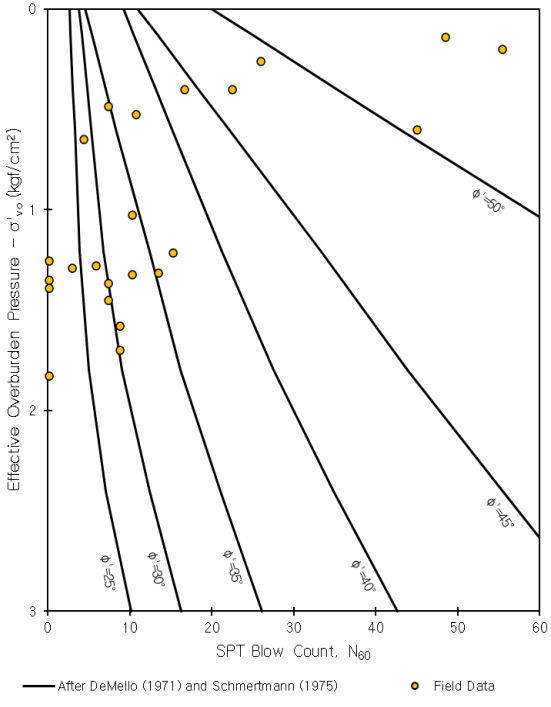
The selected strength envelope (c' = 0 tsf and φ' = 34°) is plotted with the CU data from tests performed on undisturbed samples of the Fly Ash as part of the Exploratory Drilling SAR and historical investigations (MACTEC 2009 and Geosyntec 2010a). The data was obtained using maximum effective principal stress ratio as the failure criterion. The labels on Figure 3 indicate from which boring the samples were obtained.

In total, data is available from 10 CU triaxial compression tests. Overall, the data is grouped along a general linear trend. The assigned strength parameters were selected by fitting the CU data per the two-thirds best fit rule.

Compared to the strengths used in the historical stability analyses, the assigned strength parameters (c' = 0 tsf and φ' = 34º) in this analysis are slightly higher. The Initial and Supplemental Assessments of the Slope Stability of the East Dike used a friction angle of 25 degrees based on earlier assessments of "Soft Pond Ash", however it is noted that "these values are conservative compared to the laboratory testing results" (Geosyntec 2010a and 2012). In the historical Polishing Pond stability, the Bottom Ash and Fly Ash were modeled as a single material with a friction angle of 32 degrees.

Drained strength parameters were also estimated using empirical correlations for standard penetration test (SPT) (DeMello 1971 and Schmertmann 1975) and CPT (Robertson and Campenella 1983) data. The data, which is from historical field explorations, is shown on Figure 4 with the correlations. While acknowledging the significant data scatter, the data from both correlations was compiled and produced an average drained friction angle of 35 degrees, as shown on Figure 4.

Figure 4. Empirical correlations for the drained friction angle for Fly Ash based on SPT data (left) and CPT data (center). The data is presented together versus elevation (right), with the average drained friction angle of 35 degrees shown.



Duncan, J. M, and Wright, S. G. (2005). Soil Strength and Slope Stability. John Wiley and Sons, Hoboken, New Jersey.

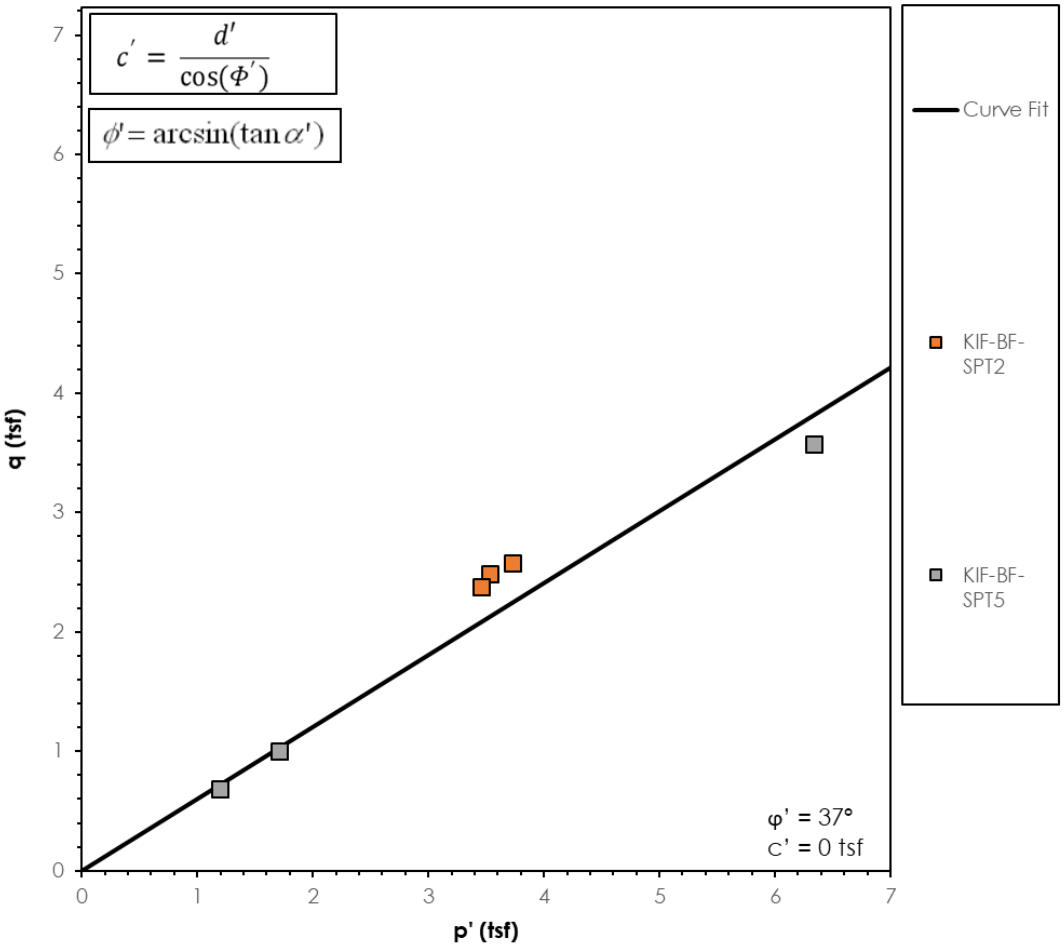
4.1.3.3 Bottom Ash

Drained strength (effective stress) parameters for the Bottom Ash under static, long-term conditions are presented on Figure 5. Determination of these parameters is described below.

Figure 5. Drained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Bottom Ash



The selected strength envelope (c' = 0 tsf and φ' = 37°) is plotted with the CU data from tests performed on undisturbed samples of the Bottom Ash as part of historical investigations (AECOM 2016a). The data was obtained using maximum effective principal stress ratio as the failure criterion. The labels on Figure 5 indicate from which boring the samples were obtained.

In total, data is available from six CU triaxial compression tests. Overall, the data generally plots along a linear trend. Based on the scatter of the CU data and a relatively small data set, an exact two-thirds fit could not be achieved. The assigned strength parameters were selected by approximating a two-thirds fit.

The assigned strength parameters (c' = 0 tsf and φ' = 37º) are higher than what was used in historical stability analyses. The Initial and Supplemental Assessments of the Slope Stability of the East Dike used a friction angle of 30 degrees based on limited data (Geosyntec 2010a and 2012). The historical Polishing Pond stability analysis did not delineate between the Fly Ash and Bottom Ash materials and modeled them as one material with an assigned friction angle of 32 degrees (AECOM 2016b).

4.1.3.4 Cover Material

The Cover Material can generally be classified as a fat clay with sand. The selected strength (φ' = 19º and c'=0) is based on typical values (Figure 3 in Appendix D). The Cover Material is modeled with a lower drained strength (φ' = 16º and c'=0) in the global stability analysis to account for the geosynthetics interface in the cover system.

4.1.3.5 Filter Materials

The Filter material is composed of both ASTM C33 Sand and TDOT No. 78 stone used to create the reverse graded filter. The drained strengths for the material (φ' = 33º and c' = 0) were selected based on typical values and correlations relating classification and dry unit weight to internal friction angle (Naval Facilities Engineering Command 1986), shown in Appendix D.

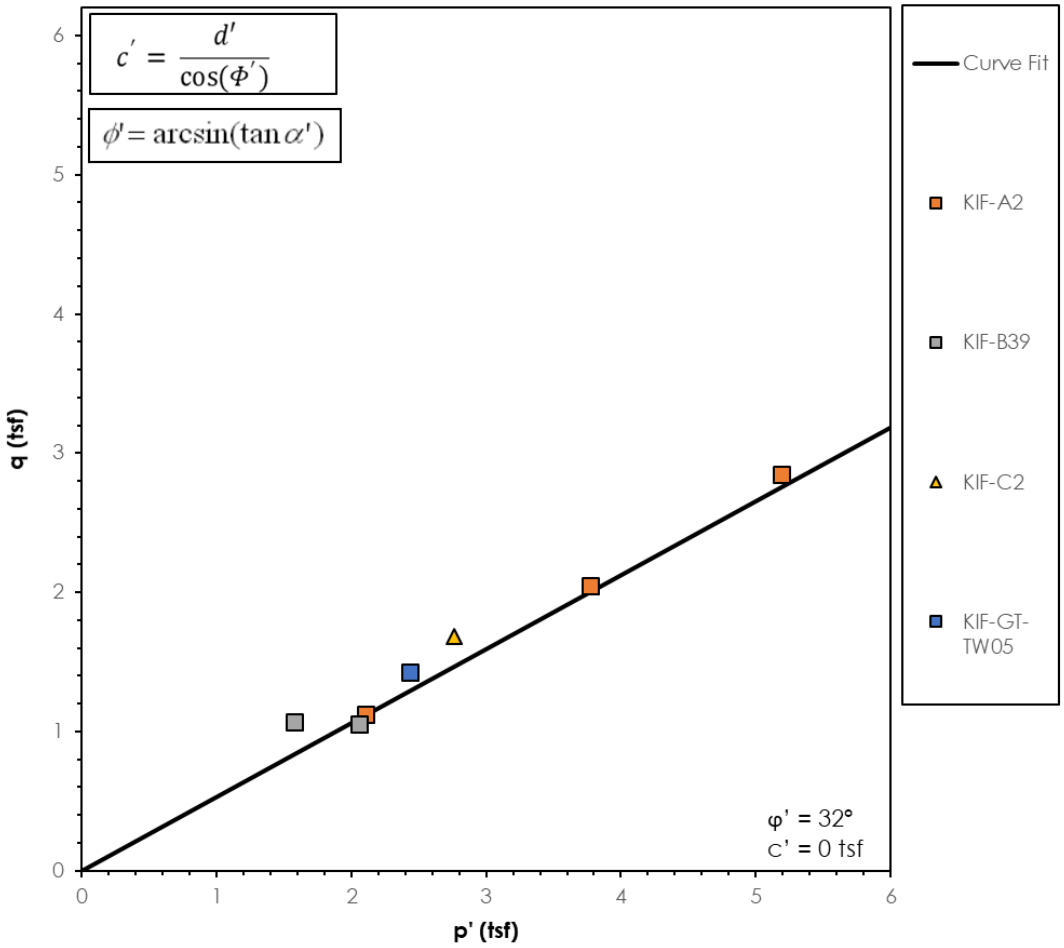
4.1.3.6 Riprap

A drained friction angle of φ' = 40º was selected (with c' = 0) based on typical values (Appendix D).

4.1.3.7 Subunit 1

Drained strength (effective stress) parameters for Subunit 1 under static, long-term conditions are presented on Figure 6. Determination of these parameters is described below.

Figure 6. Drained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Subunit 1



The selected strength envelope (c' = 0 tsf and φ' = 32º) is plotted with the CU data from tests performed on undisturbed samples of Subunit 1 as part of the Exploratory Drilling SAR and historical investigations (MACTEC 2009 and Geosyntec 2010a and 2010b). The data was obtained using maximum effective principal stress ratio as the failure criterion. The labels on Figure 6 indicate from which boring the samples were obtained.

In total, data is available from seven CU triaxial compression tests. Overall, the data is grouped along a linear trend. The assigned strength parameters were selected by fitting the CU data per the two-thirds best fit rule.

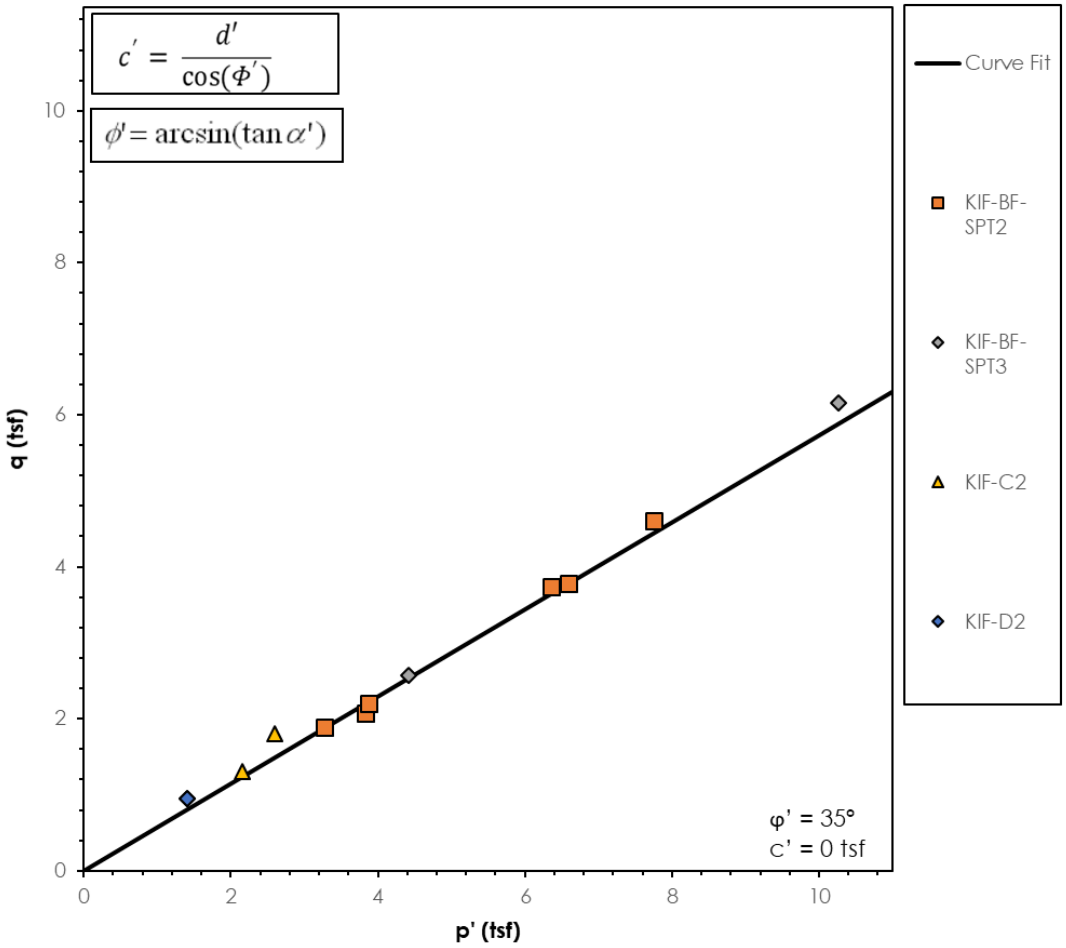
The selected strength parameters (c' = 0 tsf and φ' = 32º) compare well to the strength parameters used in the Polishing Pond Stability Analysis (AECOM 2016a). The report used a drained friction angle of 33 degrees derived from laboratory data; however, the foundation soil was modeled as one material rather than divided into subunits. The Initial Assessment of the Slope Stability of the East Dike (Geosyntec 2010a) used a drained friction angle of 30 degrees based on laboratory data. The Supplemental

Assessment of the Slope Stability of the East Dike (Geosyntec 2012) used only cohesion (0.9 tsf) to represent the strength for Subunit 1; the strength was calculated using correlations for CPT data. The Stilling Pond Updated Seismic Performance (Stantec 2020) assigned a similar drained friction angle of 35 degrees to Subunit 1, based on laboratory data.

4.1.3.8 Subunit 2

Drained strength (effective stress) parameters for Subunit 2 under static, long-term conditions are presented on Figure 7. Determination of these parameters is described below.

Figure 7. Drained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Subunit 2



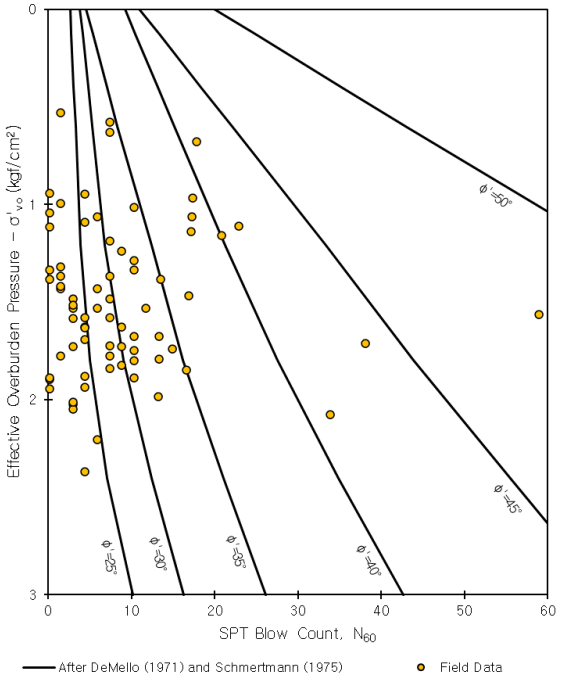
The selected strength envelope (c' = 0 tsf and φ' = 35º) is plotted with the CU data from tests performed on undisturbed samples of Subunit 2 as part of the historical investigations (Geosyntec 2010b and AECOM 2016b). The data was obtained using maximum effective principal stress ratio as the failure criterion. The labels on Figure 7 indicate from which boring the samples were obtained.

In total, data is available from 12 CU triaxial compression tests. Overall, the data is grouped along a linear trend. The assigned strength parameters were selected by fitting the CU data per the two-thirds best fit rule.

Compared to the strengths used in the historical stability analyses, the assigned strength parameters (c' = 0 tsf and φ' = 35º) in this analysis are slightly higher. The Initial and Supplemental Assessments of the Slope Stability of the East Dike conservatively used a drained friction angle of 30 degrees but reported CPT data that correlated to a friction angle of approximately 35 degrees (Geosyntec 2010a and 2012). In the Polishing Pond Stability Analysis (AECOM 2016a), the foundation soil was modeled as a single material with a drained friction angle of 32 degrees. The Stilling Pond Updated Seismic Performance (Stantec 2020) assigned a drained friction angle of 26 degrees to Subunit 2, based on Figure 3 in Appendix D.

Drained strength parameters were also estimated using empirical correlations for SPT (DeMello 1971 and Schmertmann 1975), and CPT (Robertson and Campenella 1983) data. The data, which is from historical field explorations, is shown on Figure 8. The data from both correlations was compiled and produced an average drained friction angle of 32 degrees, not significantly different from the selected value of 35 degrees that was based on the laboratory CU data. The average of the correlations is also shown on Figure 8.

Figure 8. Empirical correlations for the drained friction angle for Subunit 2 based on SPT data (left) and CPT data (center). The data is presented together versus elevation (right), with the average drained friction angle of 32 degrees shown.



Duncan, J. M. and Wright, S. G. (2005). Soil Strength and Slope Stability. John Wiley and Sons, Hoboken, New Jersey.

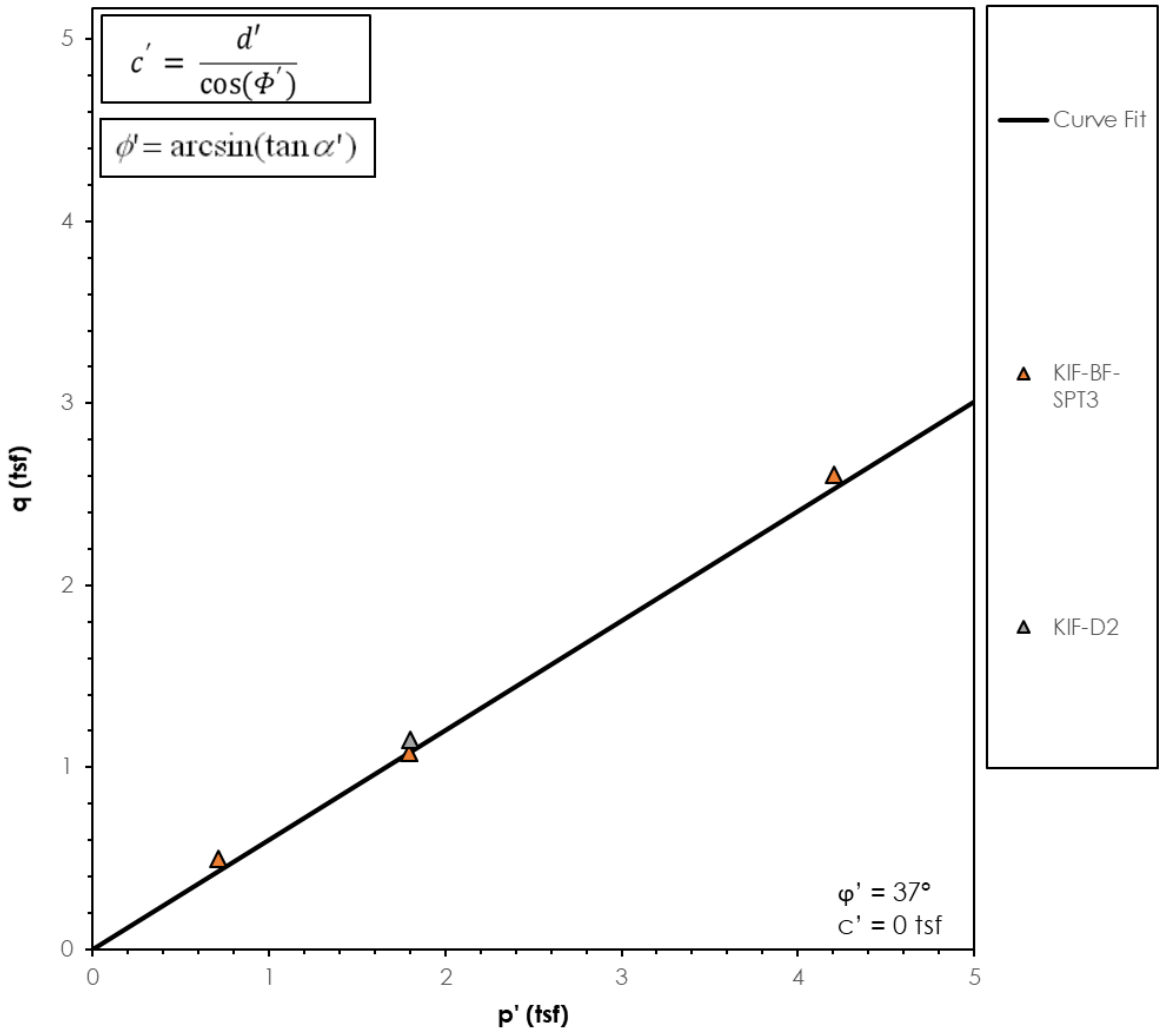
4.1.3.9 Subunit 3

Drained strength (effective stress) parameters for Subunit 3 under static, long-term conditions are presented on Figure 9. Determination of these parameters is described below.

Figure 9. Drained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Subunit 3



The selected strength envelope (c' = 0 tsf and φ' = 37º) is plotted with the CU data from tests performed on undisturbed samples of Subunit 3 as part of the historical investigations (Geosyntec 2010b and AECOM 2016b). The data was obtained using maximum effective principal stress ratio as the failure criterion. The labels on Figure 9 indicate from which boring the samples were obtained.

In total, data is available from four CU triaxial compression tests. Overall, the data generally plots along a linear trend. The assigned strength parameters were selected by fitting the CU data per the two-thirds best fit rule.

The assigned strength parameters (c' = 0 tsf and φ' = 37º) are similar to the historical Initial and Supplemental Assessments of the Slope Stability of the East Dike (Geosyntec 2010a and 2012), which used a drained friction angle of 35 degrees. CPT correlations performed as part of the analysis resulted in a friction angle range of 37 to 43 degrees. In the historical Polishing Pond stability analysis, the foundation soil was modeled as a single material, which had a drained friction angle of 32 degrees (AECOM 2016b). The Stilling Pond Updated Seismic Performance (Stantec 2020) assigned a similar drained friction angle of 34 degrees to Subunit 3, based on SPT and CPT data.

4.1.4 Shear Strength of Bedrock

The dip of the shale bedrock is to the southeast, which is in the outboard direction relative to the East Dike. This orientation of the bedding planes increases the resistance to sliding within the bedrock. Based on the depth to bedrock, bedding plane orientation, and relative material strengths of the overlying soils, the shale bedrock is modeled as impenetrable in these analyses. See Section 6.1.4 for discussion on how impenetrable materials are considered in the global stability models.

4.2 ANALYSIS CROSS SECTIONS

The stability analyses are performed for the specific cross sections listed in Table 5 and shown on Figure 10. Per the Stability SAP, the selected locations represent critical cross sections based on reviews of previous stability analysis results, subsurface stratigraphy, material properties, and structure geometry. If the previously used cross sections were not considered representative for the new analyses, sections were updated or new cross sections were developed using available site-specific data (including data from the Exploratory Drilling SAR). The following subsections present the specific basis for the selection of each section.

Table 5. Analyzed Cross Sections at KIF Plant

CCR Unit	Cross Section	Notes
Sluice Trench and Ballfield East of Sluice Trench	A-A'	Southwest portion of the East Dike near the intake channel at KIF Plant
Sluice Trench and Ballfield East of Sluice Trench	Polishing Pond	Central portion of the East Dike, including the Polishing Pond but excluding the Engineered Wetlands
Sluice Trench and Ballfield East of Sluice Trench	Typical (veneer only)	Representative section for veneer stability analysis; steep portion of the Polishing Pond section.

The previous global slope stability analysis results (Geosyntec 2010a, 2010b, and 2012, AECOM 2016a) for the Sluice Trench and Ballfield East of the Sluice Trench were reviewed to identify the critical cross section(s) for the static, long-term loading condition. Geosyntec (2010a, 2010b, and 2012) included static, long-term global stability analyses for four cross sections (Sections A, B, C, D) at the Sluice Trench and Ballfield East of the Sluice Trench. The lowest factors of safety for global stability (for the existing condition at that time) were reported at Section A (FS=1.7) and Section B (FS=1.6). During the planning and design of the Polishing Pond, AECOM (2016a) analyzed the "Polishing Pond" cross section, which is located near Geosyntec's Section B. For the static long-term global stability, the AECOM (2016a) analysis considered a slip surface intercepting the Polishing Pond pool (FS=3.8) and a slip surface limited to the outboard toe of the East Dike (FS=2.1), so the results are not directly comparable to the slip surface criteria used herein. Since the previous analyses, the Polishing Pond has been constructed and the

Sluice Trench and Ballfield East of Sluice Trench has been regraded (including fill placed between the Polishing Pond and the East Dike) and capped with geosynthetics and cover soil (AECOM 2019). The outboard slope of the East Dike was also modified for seepage mitigation purposes (AECOM 2017). Based on the historical analysis results and the current unit geometry, Section A-A' and the "Polishing Pond" were selected as the critical cross sections to represent the static, long-term global stability for existing conditions at the Sluice Trench and Ballfield East of Sluice Trench.

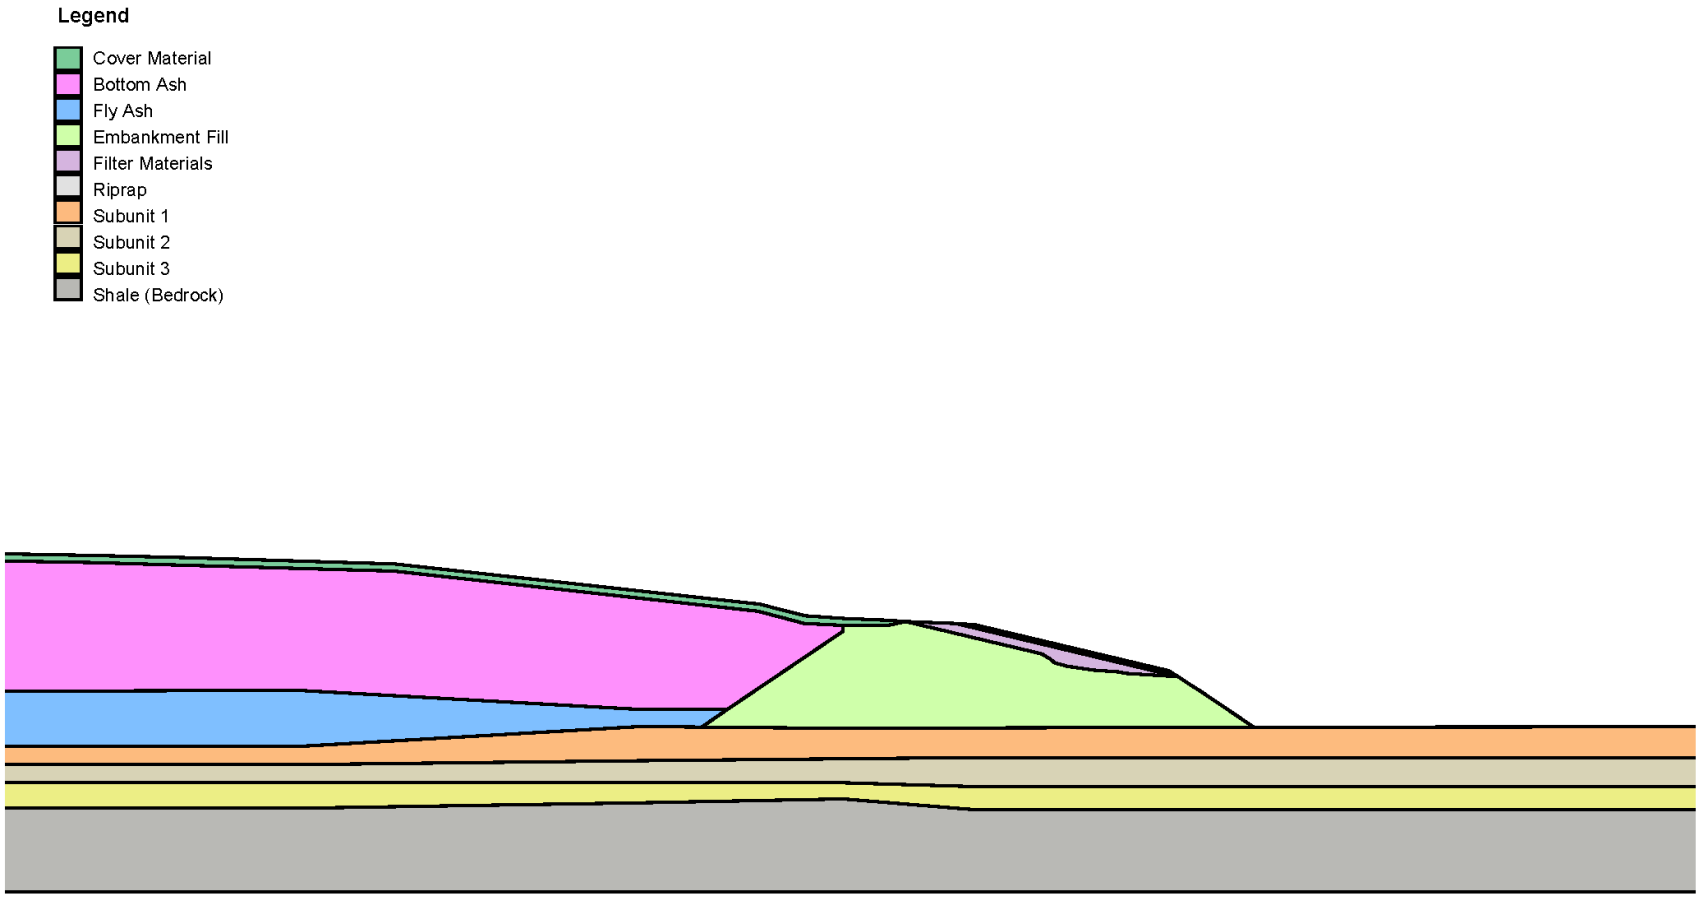
Figure 10. Cross section locations

4.2.1 Cross Section A-A': Basis for Selection

Cross section A-A' was selected to represent the typical slope geometry of the portion of the East Dike near the intake channel. This section was previously analyzed by Geosyntec (2010a and 2012). Since the previous analyses, the Sluice Trench and Ballfield East of Sluice Trench has been regraded and capped with geosynthetics and cover soil (AECOM 2019). The outboard slope of the East Dike was also modified for seepage mitigation purposes (AECOM 2017).

The geometry of the groundline was developed by combining the plant-wide LiDAR survey, completed in 2017, and the top of ground survey (i.e., as-built survey) completed as part of the seepage mitigation construction at the East Dike. The original design drawings depict the geometry and extents of the material used in the construction of the East Dike, which is comprised of lean clay fill, with some shale fragments. The outboard face of the dike has a reverse graded filter, which consists of Filter Materials between the Embankment Fill and Riprap. The Cover Material represents the cap system installed over the Fly Ash and Bottom Ash materials on the inboard side of the East Dike. The section is underlain by alluvial foundation soil, beginning with an alluvial clay (Subunit 1) transitioning to silty sand (Subunits 2 and 3). Figure 11 shows the analysis section with the various materials color-coded for ease of review.

Figure 11. Materials in Stability Analysis Section A-A

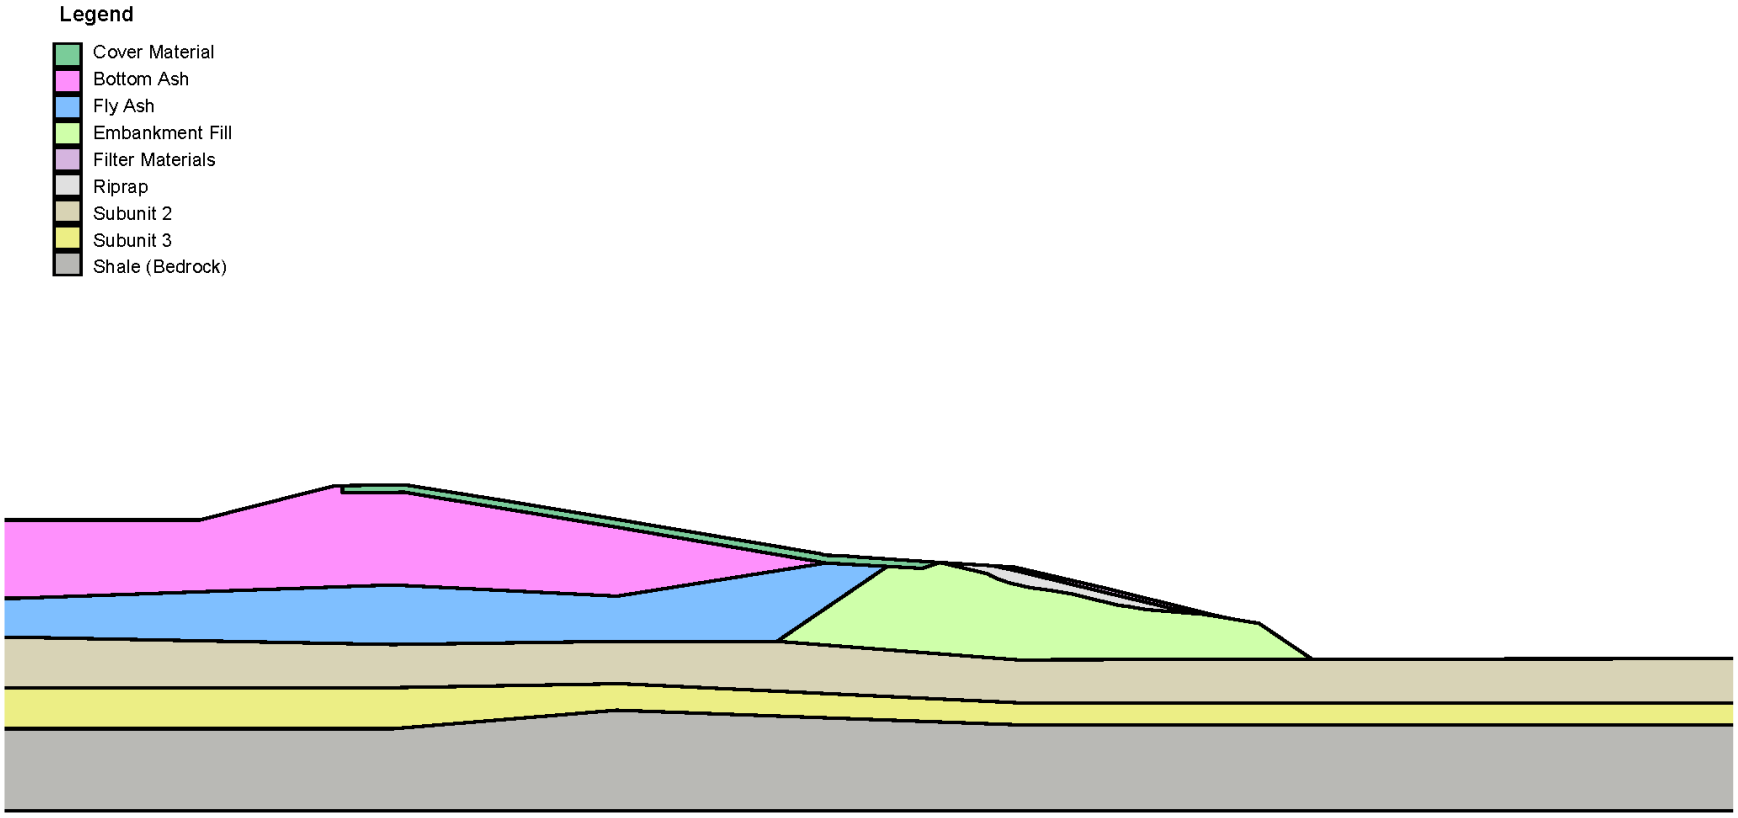


4.2.2 Cross Section “Polishing Pond”: Basis for Selection

Cross section “Polishing Pond” was selected to represent the typical section of the East Dike that includes the Polishing Pond but excludes the buttressing effect of the Engineered Wetlands. This section was previously analyzed by AECOM (2016a) during the planning and design of the Polishing Pond; however, since the previous analyses, the Sluice Trench and Ballfield East of Sluice Trench has been regraded (including fill placed between the Polishing Pond and the East Dike) and capped with geosynthetics and cover soil (AECOM 2019). The outboard slope of the East Dike was also modified for seepage mitigation purposes (AECOM 2017).

Similar to Section A-A’, the geometry was derived from previous surveys of the area and historical design drawings. The previous surveys of the area include the top of subgrade and top of grade completed as part of the seepage mitigation construction of the East Dike, in addition to the LiDAR survey of KIF Plant completed in 2017. Additionally, the record drawings for the newly constructed Polishing Pond were used to update the slope and pond geometry. The outboard face of the dike also has a reverse-graded filter, which consists of Filter Materials placed on the outboard face of the Embankment Fill and covered with Riprap. The Polishing Pond was constructed overtop of the Fly Ash and Bottom Ash, which is retained by the East Dike. The section is underlain by alluvial foundation soil, beginning with alluvial sandy silt (Subunit 2) and transitioning to a silty sand (Subunit 3) above bedrock. As noted in Section 4.1.1.7, Subunit 1 is generally absent in this vicinity and was not modeled. Figure 12 shows the analysis section with the various materials color-coded for ease of review.

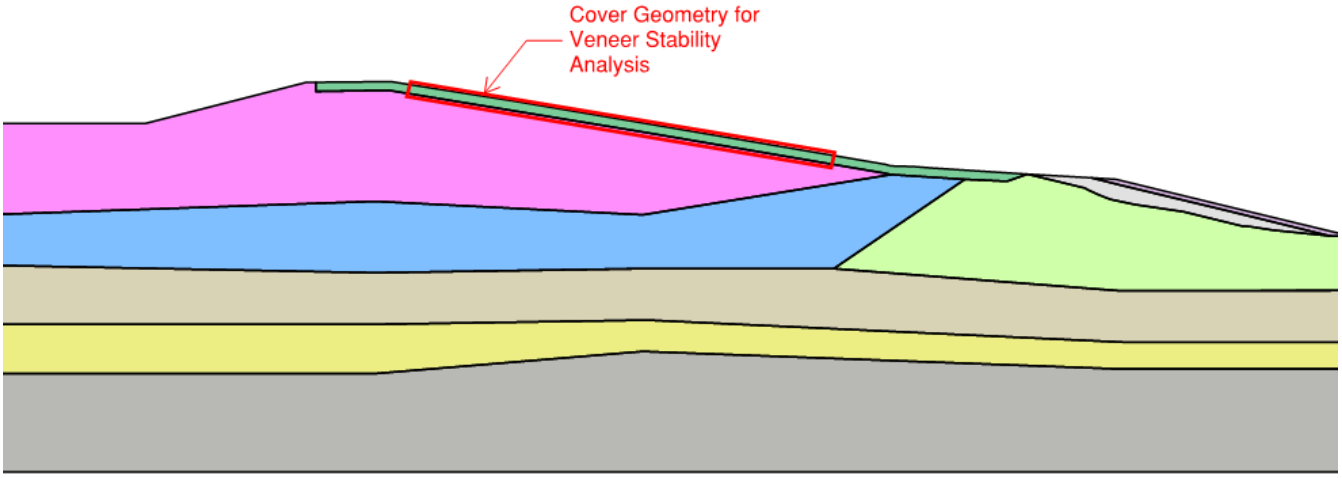
Figure 12. Materials in Stability Analysis Section "Polishing Pond"



4.2.3 Typical Section for Veneer Stability: Basis for Selection

The veneer stability was evaluated at the steepest section within the unit (Figure 13), along the Polishing Pond section, with the 2.0 ft of soil above the geosynthetic components, where the mid-slope angle is 10 degrees and the mid-slope height is 11.2 ft above the access road.

Figure 13. Selected geometry for Veneer Stability analyses



5.0 LOADING CONDITIONS AND ACCEPTANCE CRITERIA

5.1 LOAD CASES, PHASED ASSESSMENT, AND ACCEPTANCE CRITERIA

The load cases, phased assessment, and acceptance criteria presented here were approved in the EIP (Stantec 2018b). The Stability SAP (2018a) contains a detailed explanation of the basis for the load cases and acceptance criteria.

The load cases to be evaluated in the stability analyses are based on conventional practice and appropriate industry standards for landfills and surface impoundments, as applicable.

- Static, long-term (i.e., normal operation conditions) global stability
- Static, long-term veneer (i.e., final cover) stability.

The stability analyses defined in the Stability SAP are performed using a phased assessment process. Initial phases employ available site information, simplified analysis methods, and more conservative acceptance criteria. If acceptable performance is demonstrated, the analyses for the particular load case(s) are then complete. If not, the next phase may include collection of additional site information and/or more advanced analysis methods. Less conservative acceptance criteria may be utilized, commensurate with the improved site characterization. The process may continue through multiple phases, as outlined in the Stability SAP. The use of a phased approach is consistent with industry standard engineering practices.

The load cases and acceptance criteria presented herein (Table 6) apply specifically for the TDEC Order. The same CCR units may also be subject to other requirements (which may be more or less stringent) for compliance with other regulations such as state permitting, CCR Rule, etc. This Stability SAR documents Phase 1 TDEC Order stability assessments as noted in Table 1. The process for a Phase 1 assessment is as follows:

Phase 1 Assessment

- Use available geotechnical data SPT, CPT, laboratory testing, etc.
    - Where geotechnical data is insufficient, collect supplemental data
- Compute static, long-term factor of safety (global, FS_{static} and veneer, $FS_{static\text{-}veneer}$ slope stability)
- Performance is acceptable if the following criteria are met
    - $FS_{static} \geq 1.5$
    - $FS_{static\text{-}veneer} \geq 1.5$
- If any load cases do not meet criteria, go to Phase 2 (refer to Stability SAP).

Refer to the Stability SAP (Stantec 2018a) for discussion of other phases of stability assessment.

Table 6. Summary of Load Cases and Acceptance Criteria

Load Case	Pool Levels	Incipient Motion	Analysis	Soil Strengths	Pore Pressures	Acceptance Criteria
Static, Long-Term, Global and Veneer	Impoundment (where applicable): Normal Operating Pool Adjacent Reservoir: Winter Pool	Inboard (Impoundments Only) and Outboard	Drained	Drained Static	Seepage for Modeled Pool Levels and/or Piezometer Data	FS ≥ 1.5

5.2 POOL LEVELS AND PORE WATER PRESSURES

Table 7 presents the pool levels and the basis of the phreatic surfaces used to predict pore pressures in the slope stability analyses.

For static, long-term load cases, the pool within an impoundment (where applicable) is the normal operating pool. The pool in the adjacent body of water (e.g., river or reservoir) is the normal operating pool (Summer or Winter Pool, whichever is more conservative) for the reservoir.

The slope stability analyses require pore water pressures for computing effective consolidation stresses, as defined for the load conditions. Pore water pressures were estimated by assigning a piezometric line to the cross section, based, in part, on available site-specific piezometer data.

Consideration of both estimated pore water pressures and adjacent reservoir pool levels (where applicable) will generally encompass the phreatic conditions that will be experienced by the unit.

Table 7. Pool Levels and Phreatic Surfaces at KIF Plant

CCR Unit	Pool Levels		Basis of Phreatic Surface
	Impoundment	Adjacent Water Body	
Sluice Trench and Ballfield East of Sluice Trench	N/A	Emory River/Intake Channel	Nearby temporary well and piezometer data. Construction records for seepage mitigation system along East Dike.

The Emory River (including the Intake Channel for the KIF Plant) is adjacent to the East Dike at each cross section. The Emory River joins the Tennessee River just downstream of the site, both of which are then impounded by Watts Bar Dam approximately 38 miles downstream from the KIF Plant. The headwater of Watts Bar Dam varies seasonally per a prescribed operating guide, which includes target elevations for Winter and Summer Pools. The annual operating guide for Watts Bar Dam targets the Winter Pool, which is approximately five feet lower than the targeted Summer Pool, from December 1 to April 1 (TVA 2020). This seasonal change is observed in the Emory River water levels at the KIF Plant, as recorded by an onsite river gauge. The Winter Pool was modeled in the stability analyses because the lower pool (compared to the Summer Pool) provides less resisting force along the outboard slope of the East Dike and thus is more conservative for slope stability analysis. For this analysis, the elevation of the Winter Pool was defined as the median elevation for the two most recent winters of daily readings during the periods of December 1, 2018 to April 1, 2019 and December 1, 2019 to April 1, 2020. This pool elevation was calculated to be 737.4 ft.

The phreatic surfaces for both sections were developed using the calculated onsite Winter Pool and piezometric data collected from temporary wells and piezometers installed at the Sluice Trench and Ballfield East of Sluice Trench. The piezometric data were obtained from TVA's geotechnical instrumentation database. Median values of available piezometric data from the past two years were used. For most instruments, the available data consisted of periodic readings from May to December 2019 and one reading from April 2020. The instruments used to create the phreatic surface for Section A-

A' include temporary well KIF-TW04 and piezometers PZ-A1 and PZ-A2 (Geosyntec 2010a). The instruments used to create the phreatic surface for the Polishing Pond Section include the temporary wells KIF-TW04 and KIF-TW05, and piezometers PZ-B1, PZ-B2, and PZ-B3 (Geosyntec 2010a). The instruments are located between the interior of the adjacent Interim Ash Staging Area and the crest of the East Dike. Generally, the instruments used for the phreatic surface at the Polishing Pond section were southwest of the section. The instruments used for the phreatic surface at Section A-A' generally aligned with the cross section. The piezometric surface at the outboard face of the East Dike was controlled by the invert elevation of the seepage collection pipe at each section, as defined in construction documentation from the KIF East Dike Seepage Mitigation project (AECOM 2017).

It should be noted that the Polishing Pond (Figure 1), located partially within the boundaries of the Sluice Trench and Ballfield East of Sluice Trench CCR unit, is lined with geomembrane. Thus, the water in this pond is hydraulically isolated from the subsurface and does not influence the underlying phreatic surface. However, the weight of the water within the pond was included as a surcharge load in the Polishing Pond analysis section. The surcharge load was modeled for a pond elevation of 769.2 ft, which is the designed normal pool (AECOM 2016b).

6.0 METHODOLOGY

6.1 GENERAL

6.1.1 Software

Slope stability is evaluated using conventional, limit equilibrium methods as implemented in the GeoStudio SLOPE/W 2016 software (GEO-SLOPE 2015). Available from GEO-SLOPE International, Ltd., of Calgary, Alberta, Canada (www.geo-slope.com), SLOPE/W is a special-purpose computer code designed to compute the stability of earth slopes using two-dimensional, limit equilibrium, method of slices analyses. SLOPE/W 2016, version 8.16, is used for the analyses described herein. With SLOPE/W, the distribution of pore water pressures within the earth mass may be mapped directly from the results of a SEEP/W analysis.

6.1.2 Assumed System(s) of Slice Forces

Limit equilibrium methods for evaluating slope stability consider the static equilibrium of a soil mass above a potential failure surface. In conventional, two-dimensional methods of analysis, the slide mass above an assumed failure surface is split into vertical slices. Stresses are evaluated along the sides and base of each slice. The factor of safety against a slope failure (FS_{slope}) is defined as:

$$FS_{slope} = \frac{shear\ strength\ of\ soil}{shear\ stress\ required\ for\ equilibrium} \qquad \textbf{Equation 1}$$

where the strengths and stresses are computed along a defined failure surface, on the base of the vertical slices. The shearing resistance at locations along the potential slip surface is computed, with appropriate Mohr-Coulomb strength parameters, as a function of the total or effective normal stress.

Spencer's solution procedure (Spencer 1967), which satisfies the conditions of equilibrium for each slice, is used in this study. Key assumptions and features of Spencer's method include (United States Army Corps Engineers 2003; Duncan and Wright 2005):

- Interslice forces are assumed to have the same inclination angle with respect to the horizontal. The inclination is computed as part of the solution.
- The normal force on the base of each slice is assumed to act at the center of the base
- A trial and error solution is required, to solve for equilibrium
- Force and moment equilibrium are satisfied for each slice, and the overall slide mass
- Circular and noncircular potential failure surfaces can be evaluated

- The procedure computes FS_{slope} for an assumed failure surface. A search must be made to find the critical slip surface corresponding to the lowest FS_{slope}.

6.1.3 Optimization Scheme to Define Critical Rupture Surface

Once a critical slip surface is identified by the automated search routine, the "optimization" feature in SLOPE/W is used to consider the possible effects of localized changes in the slip surface. The code divides the critical slip circle into linear segments, then moves the end points while searching for a surface that yields a lower FS_{slope}. The optimization routine will sometimes produce a slip surface with reverse curves, or one that is not otherwise kinematically logical. If the inferred, failure mechanism is not a realistic representation of slope movements, the "optimized" result is discarded.

A variety of these methods is used in searching for the critical slip surface. The details of the employed strategy are relatively unimportant, however, as different approaches usually lead to similar answers. The final failure surface, representing the critical slip surface associated with FS_{slope}, is selected by the engineer based on the analytical results, the automated search outcomes, and knowledge of the geotechnical conditions.

6.1.4 Shapes of Rupture Surfaces Considered

SLOPE/W includes several options and trial routines to facilitate the search for the critical failure surface (GEO-SLOPE 2015). In the "grid and radius" search method, a region (divided into a grid) for the circle centers and a range of possible radii are specified for the trial slip circles. The code then automatically evaluates a large number of trial circles within those parameters, searching for one circle having the lowest FS_{slope}. In the "entry and exit" method, the search considers potential slip circles that intersect the ground surface within specified ranges. Where a potential failure circle intersects a much stronger, "impenetrable" layer (such as rock), SLOPE/W automatically evaluates composite slip surface (circles with straight-line portions along the interface). Non-circular slip surfaces are considered using the "block method".

Slip surfaces are evaluated for two conditions in the analyses: failure surfaces that intercept the contained CCR and shallow (D_{min} = 10 ft) failure surfaces. See additional discussion in Section 6.1.5.

6.1.5 Consideration of Shallow Slope Instabilities

When an earth slope is comprised of a cohesionless soil, an infinite slope mechanism will have the least resistance to sliding. An infinite slope failure will result in shallow raveling of the embankment slope. Localized, shallow slips of this type can be repaired to prevent progression to a deeper sliding mechanism, such that infinite slope failures are usually considered as a potential maintenance issue. Moreover, capillary stresses (which are neglected in the analysis) in the near surface soil will create an apparent cohesion that resists shallow sliding.

In a stability analysis where the surficial soil is modeled with a strength envelope having zero cohesion (c = 0), the lowest factor of safety will be computed for shallow sliding parallel to the slope face. The slope stability analyses presented here are focused on the potential for slope failures of significant mass, which

could directly impact the safety of the CCR unit. The search for a critical slip surface in the stability analyses is thus restricted, to consider only potential surfaces where the depth (measured at the base of at least one slice) is more than 10 ft vertically below the ground surface. Shallower slip surfaces at depths less than 10 ft, representing infinite slope failures, are ignored in the analysis.

The minimum specified depth may be increased or decreased as needed to study failure mechanisms for a given slope geometry. Consideration of sliding depths less than 10 ft may be warranted on relatively short structures. Other criteria are appropriate where shallow sliding could initiate a progressive failure that would impact a significant portion of the CCR unit or critical project components. Any history of shallow slides at the CCR unit would be relevant.

In cases where shallow surface sliding is found to give the lowest safety factor, additional analyses are completed to evaluate failure surfaces that would intercept the contained CCR within the unit. The search parameters are set to find a critical slip surface that intercepts CCR within the unit.

This “CCR intercept” stability analysis will indicate a different factor of safety, for a potential failure mode that would more clearly correspond to an unacceptable CCR release condition. In reporting the stability results, the CCR intercept failures are thus given greater emphasis than the failures that do not intercept CCR.

6.1.6 Exclusion of Retrogressive Slope Failure Mechanisms

A retrogressive slope failure (sometimes called a progressive slope failure) develops as a sequence of soil movements, where an initial slide mass triggers additional movement farther up the slope. If not remediated, a retrogressive failure on a CCR unit can eventually progress to the contained CCR and lead to an uncontrolled release.

Retrogressive slope failures are not evaluated herein. If acceptance criteria are met for the load cases under consideration, a retrogressive slope failure will be unlikely. Furthermore, retrogressive failures develop over a period of time and should be identified with sufficient time for intervention to remediate the failure before the contained CCR is impacted.

6.1.7 Tension Cracks

When the soils at the head of a slip surface are assigned cohesive strength ($c > 0$) in a slope stability analysis, tensile stresses are often computed along the base of the slices in that area. In the field, tensile stress results in the opening of a tension crack, reducing the lateral stresses to zero. Because tension results in a stabilizing force at the head of the slide mass, it is unconservative to have tensile stresses between the slices in a slope stability analysis. This problem is discussed by Duncan and Wright (2005).

When tensile stresses are reported in the stability calculation, a vertical tension crack is introduced into the analysis at the ground surface. The crack depth is increased until tensile stresses (negative normal stresses on the base of a slice) are no longer indicated. The depth of the tension crack (d_{crack}) should not exceed this theoretical maximum value:

$$(d_{crack})_{max} = \frac{2\,c_d}{\gamma_m \tan(45 - 0.5\phi_d)}$$ **Equation 2**

Here, γ_m is the moist unit weight, and c_d and ϕ_d are the developed shear strength parameters ($c_d = c / FS_{slope}$, $\tan\phi_d = \tan\phi / FS_{slope}$), for the upper soil layer at the head of the slip surface.

For earthquake load cases, tension cracks are assumed to be dry. For other load cases, an incipient failure may coincide with rain and surface runoff, which would fill a tension crack with water and create an additional lateral force on the slide mass. Tensions cracks are thus assumed to be full of water for these load cases.

6.1.8 Drained versus Undrained Analyses

Conventional, geotechnical stability is evaluated for only two bounding conditions:

- Drained conditions, where the pore pressures are assumed to be unchanged, shear strengths are computed based on the effective stress at failure, and effective stress stability analyses are used
- Undrained conditions, where the final pore pressures (including pore pressures induced by shearing) are unknown, shear strengths are constant or computed based on the effective consolidation stress, and total stress analyses are used.

The inherent assumptions for each condition are summarized in Table 8. The type of analysis to be used for each load case is defined in Section 5.1.

When setting up the slope stability analysis, each material zone is considered individually to determine which strength parameters (drained or undrained) should be assigned for a particular load case. Within an undrained, total stress stability analysis, it may be appropriate to treat some permeable material zones as fully drained (that is, assume no excess pore pressure at failure and assign effective stress strength parameters), while undrained strength parameters are specified in other zones.

The decision to treat a particular material zone as drained or undrained is based on how rapidly the loading condition develops with respect to how quickly pore pressures induced by the loading can dissipate. In most cases, clean, coarse rockfill will be fully drained under the considered loading conditions, even during seismic loading. Most other soils, including sands, will behave undrained during seismic loading. In marginal cases, the time factor (T) can be estimated to judge when a particular soil zone is drained or undrained in a particular load case (see Appendix D).

For either drained or undrained stability analyses, pore pressures are specified for each material zone consistent with how the strength parameters model the shearing resistance in that soil. The input pore pressures are used to compute the effective consolidation stresses along the trial failure surfaces. When “drained” strengths (c’, ϕ’) or “consolidated undrained” (c, ϕ) strengths are used, the shearing resistance is computed from the consolidation stresses normal to the failure surface. When undrained strengths are characterized using c/p (S_u/σ'_{vo}) ratios, the shearing resistance (S_u) is computed based on the vertical effective stress to which the soil has been consolidated at points along the slip surface. Technically, pore

pressures are not needed where "unconsolidated undrained" (S_u, $\phi = 0$) strengths are specified. Because the assigned strength is constant in this case, pore pressures input for $\phi = 0$ soils will have no impact on the slope stability solution.

In practice, it is therefore acceptable to provide steady-state pore pressures for each material for both drained, effective-stress and undrained, total-stress analyses. In each considered load case, pore pressures are computed to represent the steady-state seepage condition, prior to loading to failure (Section 6.1.9).

Table 8. Conditions for Drained versus Undrained Analyses

	Drained Condition	**Undrained Condition**	
Loading Cases (Section 5.1)	Long-Term	Pseudostatic Post-Earthquake	
Type of Stability Analysis	Effective Stress	Total Stress	
Pore Pressures at Failure	Assumed equal to steady state seepage	Unknown, cannot be predicted with confidence	
Characterization of Shear Strength	Drained, effective stress parameters	Undrained strength parameters	
Strength Parameters	c', ϕ'	S_u, $\phi = 0$	c, ϕ or S_u/σ'_{vo}
Pore Pressures used in Stability Analysis	From steady state seepage model	Pore pressures not used	From steady state seepage model

Notes:

ϕ'	drained friction angle	c'	drained cohesion
ϕ	undrained friction angle	c	undrained cohesion
S_u	shearing resistance	σ'_{vo}	vertical effective stress

6.1.9 Input Pore Pressures

The slope stability analyses require pore water pressures for computing effective consolidation stresses, as defined for the specified load conditions (Section 5.1). Pore pressures are predicted based on the depth below the assumed phreatic surface, sometimes called the piezometric line. This line illustrates the locations in the cross section at which the pore pressure is assumed to be zero. The pore pressure increases hydrostatically with distance below this line.

The pore water pressures in some stability analyses must be computed using piezometric lines. Due to software limitations, SLOPE/W cannot use mapped pressures from the SEEP/W solution for certain load cases.

A piezometric line is assumed to correspond to the phreatic line (line of zero pore pressure) predicted by SEEP/W. The phreatic line is manually digitized for input to SLOPE/W, which then computes pore pressures at any point based on the depth below this line. Some of the detailed information from the seepage analysis is thus lost because SLOPE/W cannot interpolate the nodal pore pressures from the finite element solution.

The less rigorous method, using piezometric lines to compute pore pressures, may or may not be conservative, depending on the geometry and details of the seepage problem. Little to no error occurs when seepage passes through a uniform cross section and the phreatic surface is horizontal. Greater

inaccuracies are introduced when pore pressures are computed from more steeply sloping piezometric lines.

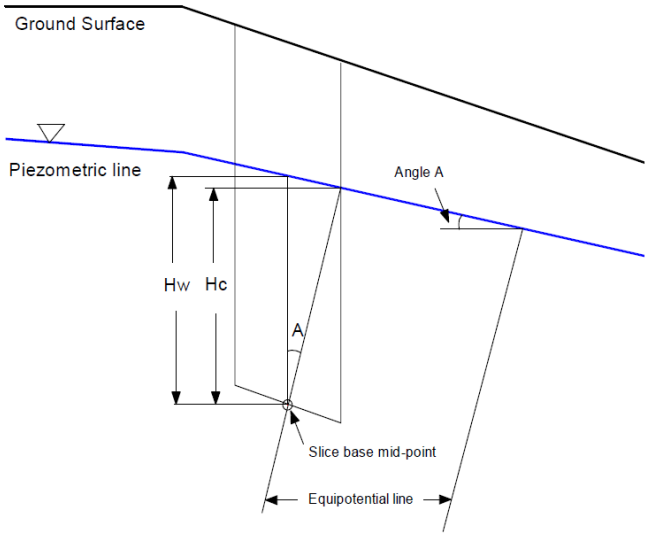
To reduce this error in the undrained analyses that use piezometric lines, an approximate “phreatic correction” is employed within SLOPE/W. Instead of computing pressures based on the vertical distance below the piezometric line, pore water pressures (u) are computed as (GEO-SLOPE 2015):

$$u = \gamma_w H_c = \gamma_w H_w \cos^2 A \qquad \textbf{Equation 3}$$

The unit weight of water is γ_w. The heights used to compute the pore pressure at the base center of the slice with and without correction are H_c and H_w, respectively. The variables in Equation 3 are further defined on Figure 14. The correction factor ($\cos^2 A$) is one for a horizontal phreatic surface (A = 0°) and approaches zero as the phreatic surface approaches vertical (A = 90°).

Pore water pressures above the phreatic line are assumed to be zero. That is, pore pressures within the unsaturated material are set to zero so that no additional soil strength along the slip surface is attributed to suction pressures (capillary tension).

Figure 14. Phreatic Surface Correction (from GEO-SLOPE 2015)



6.1.10 Single-Stage Analyses

In a single-stage slope stability analysis, the sliding resistance and factor of safety are computed concurrently, for a given failure surface, problem geometry, and applied load. This approach is correct when the soil mass consolidates under the loading conditions being evaluated for stability. Here, single-stage stability analyses are appropriate for the drained, effective stress analyses. In each of these cases,

the steady state seepage conditions and applied external loads occur under the same conditions (geometry and applied load) and can be modeled in one limit equilibrium calculation.

6.2 STATIC STABILITY

6.2.1 Long-Term, Global Stability

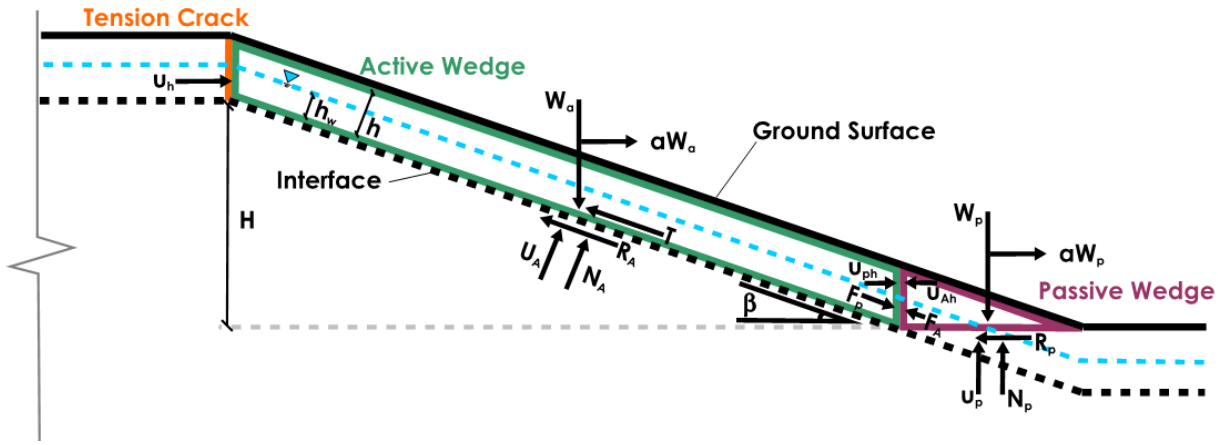
Long-term, global stability is assessed using the methods described in Section 6.1.

6.2.2 Long-Term, Veneer Stability

Veneer stability analyses were used to assess the potential for sliding in the cap system of the CCR unit. The geometry of the veneer stability problem is relatively simple and can be represented with a series of force balance equations.

An equation for the factor of safety for veneer stability was developed following the procedures outlined in Koerner and Soong (2005). A free body diagram (Figure 15) illustrates the forces considered in the analysis. The derivation and definitions of the variables used in the veneer stability derivation are provided in Section 2.0 of Appendix C.

Figure 15. Free body diagram representing veneer stability problem



7.0 RESULTS

The global stability results presented (and compared to the acceptance criteria) are those in which the critical failure surface intercepts the contained CCR within the unit (See Section 6.1.5). The global stability analysis models and critical failure surfaces are shown in Appendix B. Calculations for the veneer stability results presented below are included in Appendix C.

7.1 STATIC STABILITY

7.1.1 Long-Term, Global and Veneer Stability

The static, long-term, global stability of each section was analyzed for each cross section. The static, long-term, veneer stability was analyzed for the typical geometry of the cover system. The results of the static stability analyses, with the minimum required FS, are summarized in Table 9.

Table 9. Long-Term, Static Stability Results at KIF Plant

CCR Unit	Analysis Type	Cross Section	FS Required	FS Sliding
Sluice Trench and Ballfield East of Sluice Trench	Global	A-A’	≥ 1.5	1.9
Sluice Trench and Ballfield East of Sluice Trench	Global	Polishing Pond	≥ 1.5	2.4
Sluice Trench and Ballfield East of Sluice Trench	Veneer	Typical	≥ 1.5	1.8

8.0 VARIATIONS

The proposed scope and procedures for the stability analysis were outlined in the SAP and QAPP, as detailed in the sections above. Variations in scope or procedures discussed with TDEC and/or TVA are described in the following sections. As discussed below, these variations do not impact the overall usability and representativeness of the dataset provided in this SAR for the stability analysis activities at the KIF Plant.

8.1 VARIATIONS IN SCOPE

No variations in scope occurred during stability analysis activities.

8.2 VARIATIONS IN PROCEDURES

Variations in procedures occurring during the stability analysis are provided below.

- This SAR summarizes activities completed to meet the objectives of the Stability SAP (Stantec 2018a), for applicable static load cases. Seismic load cases (if any) required by the SAP are documented in a separate Seismic Stability SAR. This change in procedure was approved by TDEC.

9.0 SUMMARY

The objective of this study was to document the execution of the Stability SAP (Stantec 2018a) and to serve as part of the underlying basis for the EAR. The SAP specified how new and updated global and veneer stability analyses for the Sluice Trench and Ballfield East of Sluice Trench should be developed. Seismic load cases (if any) required by the SAP are documented in a separate Seismic Stability SAR.

The stability analyses performed as part of this SAR include the static, long-term, global and veneer analyses performed in accordance with the methods outlined in the SAP. These analyses were performed at two representative global stability cross sections and one representative veneer cross section at the Sluice Trench and Ballfield East of Sluice Trench.

The static stability results for the KIF Plant are summarized and compared to criteria in Table 9. The global stability of both cross sections and the veneer stability for the typical section exceeds the established factor of safety criteria for the static load cases.

Phase 1 stability analyses, as defined in the Stability SAP, were performed for each defined section and case. The analyses employed available site information, simplified analysis methods, and more conservative acceptance criteria. Because the analyzed cases are meeting or exceeding acceptance criteria, no subsequent phases of stability analysis are required.

Stantec has completed the Phase 1 static stability analyses at the KIF Plant in Harriman, Tennessee, in accordance with the Stability SAP as documented herein. The results are usable for reporting and evaluation in the EAR and meet the objectives of the TDEC Order EIP. The results will be evaluated along with data collected under other TDEC Order SAPs, as well as other State and CCR programs. This evaluation will be provided in the EAR.

APPENDIX C – VENEER STABILITY ANALYSIS RESULTS

Tennessee Valley Authority Kingston Fossil Plant Kingston, Roane County, Tennessee	Sluice Trench and Ballfield East of the Sluice Trench

Appendix C
Veneer Stability Analyses

Purpose:

- Analyze stability of the cover system (cap) for the Sluice Trench and Ballfield East of the Sluice Trench.
- Estimate interface strength parameters (adhesion and friction angle) for the cover materials to support the stability analysis.

Methods:

- Consider veneer (infinite slope) stability failure mode for the cover system.
- Use the method developed by Koerner and Soong (2005).

Results:

- Minimum strength parameters (adhesion and friction angle) are estimated for the cover materials.
- The veneer stability of the cap system is compared against the target FS value for static conditions.

Calculation Performed by: Stantec Consulting Services Inc.	
Prepared by: Nick Duda	*Reviewed by:* Jeff Dingrando

1. STABILITY CRITERIA

The stability of the cover system was analyzed for the conditions summarized in Table 1, as defined in the SAP. The associated acceptance criteria for minimum factor of safety (FS) are listed in the last column.

Table 1. Summary of Veneer Stability Cases and Design Criteria

Design Condition	Interface Strength	Cover Soil Strength	Saturated/ Unsaturated	Static/ Pseudostatic	Criteria for Slope Stability
Static Drained	Peak	Drained	Unsaturated	Static	FS ≥ 1.5

2. ANALYSIS METHODOLOGY

Veneer stability analyses were used to assess the potential for sliding in the cap system. The geometry of the veneer stability problem is relatively simple and can be represented with a series of force balance equations.

An equation for the factor of safety for veneer stability was developed following the procedures outlined in Koerner and Soong (2005). The derivation follows. A free body diagram (Figure 1) illustrates the forces considered in the analysis. Definitions of the variables used in the veneer stability derivation are provided in Table 2.

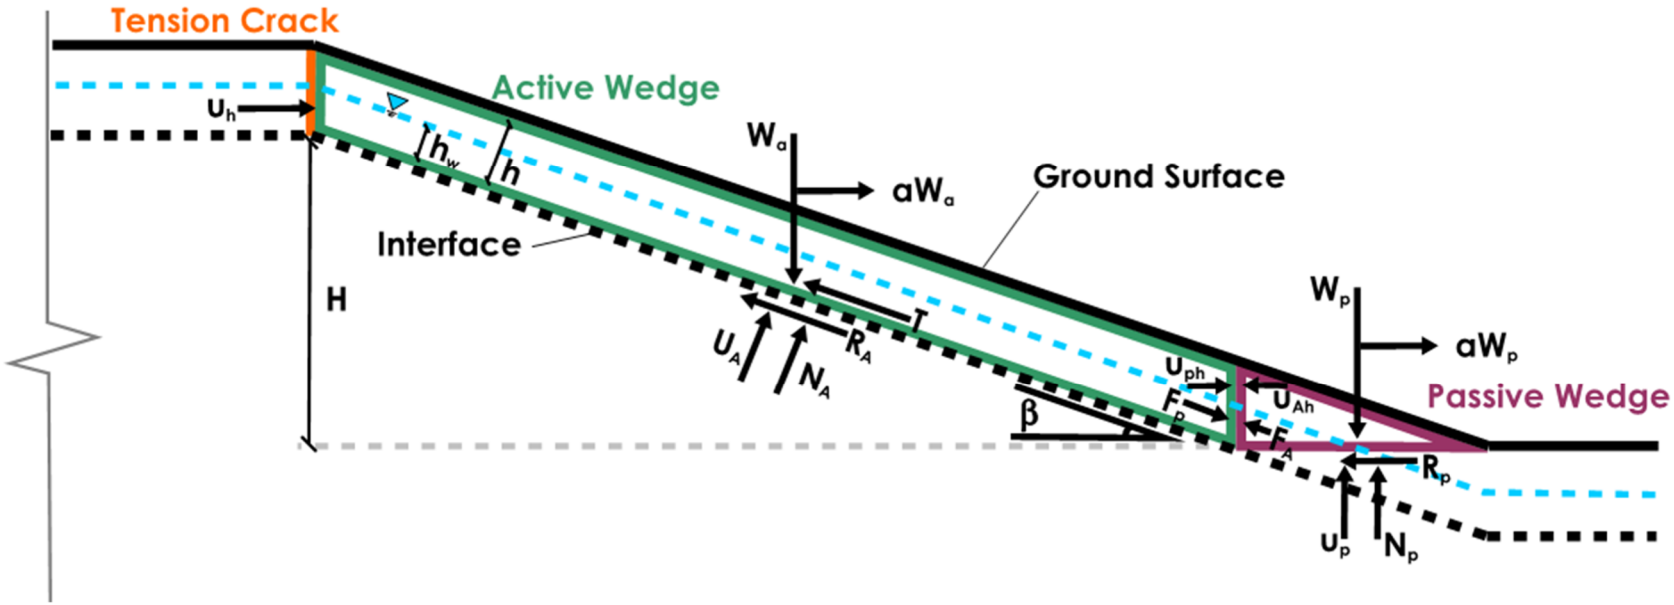

Figure 1. Free Body Diagram Representing Veneer Stability Problem

Table 2. Definition of Variables for Veneer Stability Derivation

Variable	Description
W_A	Total weight of the active wedge
W_P	Total weight of the passive wedge
N_A	Effective force normal to the active wedge failure plane
N_P	Effective force normal the passive wedge failure plane
h	Thickness of the cover soil
H	Height of the slope
β	Slope angle
a	Horizontal acceleration
u_h	Resultant of the pore pressures acting in the tension crack
u_A	Resultant of the pore pressures acting perpendicular to the slope
u_p	Resultant of the pore pressures acting perpendicular to the bottom on the passive wedge
u_{ph}	Resultant of the pore pressures acting on the inter-wedge surface to the passive wedge
u_{Ah}	Resultant o the pore pressures acting on the inter-wedge surface to the active wedge
h_w	Water height measured in the direction perpendicular to the slope
R_A	Resistance along the bottom of the active wedge
R_P	Resistance along the bottom of the passive wedge
F_A	Inter-wedge force acting on the active wedge from the passive wedge
F_P	Inter-wedge force acting on the passive wedge from the active wedge
T	Reinforcement
c_c	Cohesion of the cover soil
ϕ	Friction angle of the cover soil
γ	Moist unit weight of the cover soil
γ_{sat}	Saturated unit weight of the cover soil
Δγ	Difference between saturated and moist unit weight of the cover soil
c_a	Adhesion of the interface
δ	Friction angle of the interface
FS	Factor of safety
A, B, C, D, L, M, N	Arbitrary variables to simplify final equations

For the active wedge:

$$W_A = \left(\frac{H}{\sin\beta}\right) h_w \gamma_{sat} + \left(\frac{H}{\sin(\beta)}\right)(h - h_w)\gamma$$

$$W_A = \left(\frac{H}{\sin\beta}\right)(h_w \gamma_{sat} + h\gamma - h_w\gamma)$$

$$W_A = \left(\frac{H}{\sin\beta}\right)(h_w \Delta\gamma + h\gamma) \qquad \textbf{Equation 1}$$

$$u_h = \frac{1}{2}(\gamma_w h_w \cos\beta)\left(\frac{h_w}{\cos\beta}\right) = \frac{1}{2}\gamma_w {h_w}^2 \qquad \textbf{Equation 2}$$

$$u_{Ah} = \frac{1}{2}(\gamma_w h_w \cos\beta)\left(\frac{h_w}{\cos\beta}\right) = \frac{1}{2}\gamma_w {h_w}^2 = u_h \qquad \textbf{Equation 3}$$

$$u_A = (\gamma_w h_w \cos\beta)\left(\frac{H}{\sin\beta}\right) = \frac{\gamma_w h_w H}{\tan\beta} \qquad \textbf{Equation 4}$$

Considering force balance in the direction perpendicular to the slope:

$$N_A = W_A \cos\beta - aW_A \sin\beta - u_A - u_h \sin\beta + u_{ah} \sin\beta$$

$$N_A = W_A(\cos\beta - a\sin\beta) - u_A \qquad \textbf{Equation 5}$$

$$R_A = N_A \tan\delta + \frac{c_a H}{\sin\beta} \qquad \textbf{Equation 6}$$

Considering force balance in the direction parallel to the slope:

$$F_A = u_h \cos\beta + W_A \sin\beta + aW_A \cos\beta - u_{Ah}\cos\beta - \frac{R_a}{FS} - T$$

$$F_A = W_a(\sin\beta + a\cos\beta) - \frac{R_a}{FS} - T \qquad \textbf{Equation 7}$$

For the passive wedge:

$$W_p = \left(\frac{h}{\cos\beta}\right)\left(\frac{h}{\sin\beta}\right)\frac{\gamma}{2} + \left(\frac{h_w}{\cos\beta}\right)\left(\frac{h_w}{\sin\beta}\right)\frac{\Delta\gamma}{2}$$

$$W_p = \frac{h^2\gamma + {h_w}^2\Delta\gamma}{\sin 2\beta} \qquad \textbf{Equation 8}$$

$$u_p = \frac{1}{2}(\gamma_w h_w \cos\beta)\left(\frac{h_w}{\sin\beta}\right) = \frac{\gamma_w {h_w}^2}{2\tan\beta} \quad \textbf{Equation 9}$$

$$u_{ph} = \frac{1}{2}(\gamma_w h_w \cos\beta)\left(\frac{h_w}{\cos\beta}\right) = \frac{1}{2}\gamma_w {h_w}^2 \quad \textbf{Equation 10}$$

Considering force balance in the vertical direction

$$N_p = W_p + F_p \sin\beta - u_p \quad \textbf{Equation 11}$$

$$R_p = N_p \tan\varphi + c_c \frac{h}{\sin\beta} \quad \textbf{Equation 12}$$

Considering force balance in the horizontal direction

$$F_p \cos\beta + u_{ph} + aW_p = \frac{R_p}{FS}$$

$$FS\left(F_p \cos\beta + u_{ph} + aW_p\right) = \left(W_p + F_p \sin\beta - u_p\right)\tan\varphi + c_c \frac{h}{\sin\beta}$$

$$F_p(FS\cos\beta - \sin\beta\tan\varphi) = \left(W_p - u_p\right)\tan\varphi + c_c \frac{h}{\sin\beta} - FS\left(u_{ph} + aW_p\right)$$

$$F_p = \frac{\left(W_p - u_p\right)\tan\varphi + c_c \frac{h}{\sin\beta} - FS\left(u_{ph} + aW_p\right)}{FS\cos\beta - \sin\beta\tan\varphi} \quad \textbf{Equation 13}$$

Let $F_A = F_p$, then:

$$W_a(\sin\beta + a\cos\beta) - \frac{R_a}{FS} - T = \frac{\left(W_p - u_p\right)\tan\varphi + c_c \frac{h}{\sin\beta} - FS\left(u_{ph} + aW_p\right)}{FS\cos\beta - \sin\beta\tan\varphi} \quad \textbf{Equation 14}$$

Let also:

$$A = W_a(\sin\beta + a\cos\beta) - T \quad \textbf{Equation 15}$$

$$B = \left(W_p - u_p\right)\tan\varphi + c_c \frac{h}{\sin\beta} \quad \textbf{Equation 16}$$

$$C = u_{ph} + aW_p \quad \textbf{Equation 17}$$

$$D = \sin\beta\tan\varphi \quad \textbf{Equation 18}$$

Then Equation 14 becomes:

$$A - \frac{R_a}{FS} = \frac{B - FS * C}{FS \cos\beta - \mathrm{D}}$$

$$\frac{A * FS - R_a}{FS} = \frac{B - FS * C}{FS \cos\beta - \mathrm{D}}$$

$$A \cos\beta \, FS^2 - A * D * FS - R_a \cos\beta \, FS + R_a D = B * FS - C * FS^2$$

$$(A \cos\beta + C)FS^2 - (AD + B + R_a \cos\beta)FS + R_a D = 0 \qquad \textbf{Equation 19}$$

Let:

$$L = A \cos\beta + C \qquad \textbf{Equation 20}$$

$$M = AD + B + R_a \cos\beta \qquad \textbf{Equation 21}$$

$$N = R_a D \qquad \textbf{Equation 22}$$

Then Equation 19 becomes:

$$L * FS^2 - M * FS + N = 0$$

$$FS = \frac{M + \sqrt{M^2 - 4LN}}{2L} \qquad \textbf{Equation 23}$$

Here, FS is the factor of safety for veneer sliding within the cap.

3. ANALYZED CONDITONS

3.1. COVER GEOMETRY

The final cover system (cap) on the Sluice Trench and Ballfield East of the Sluice Trench was constructed with soil and geosynthetic materials overlying CCR (labeled CCP in historical drawings) materials, having an overall thickness of 2.0 feet. The constructed cap system is shown in Figure 3 (AECOM 2019). The veneer stability was evaluated at the steepest section within the unit, along the Polishing Pond section, with the 2.0 feet of soil above the geosynthetic components, where the mid-slope angle is 10˚ and mid-slope height of 11.2 feet above the access road.

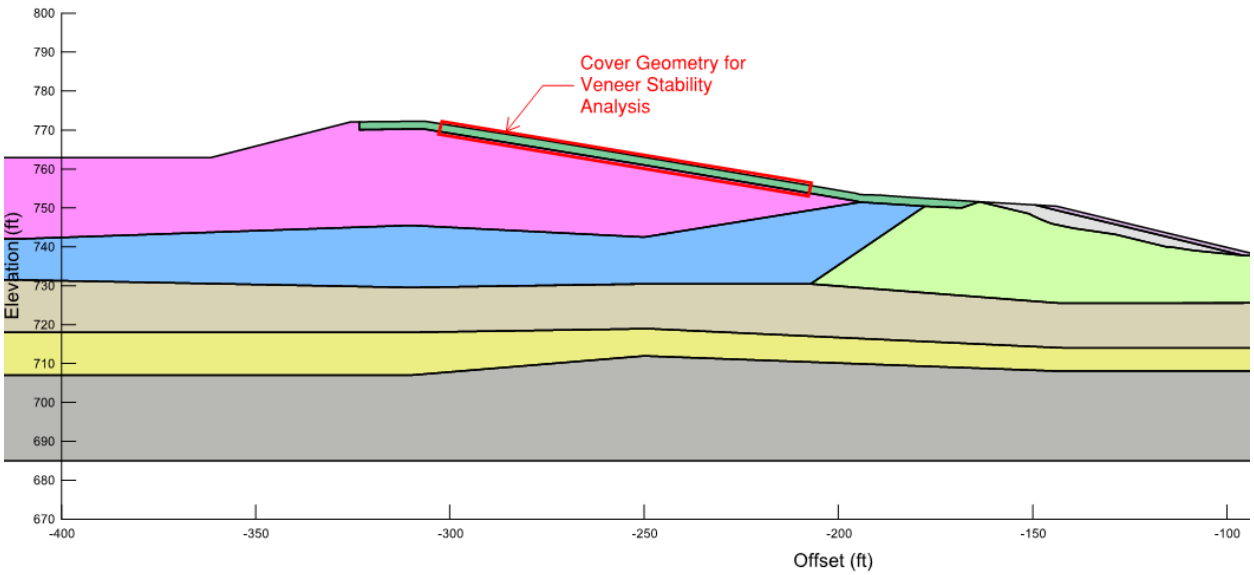

Figure 2. Selected geometry for Veneer Stability analyses

This analysis serves to evaluate the interface strengths encountered in the cap system. The results presented here apply to these interfaces (i.e., whichever has the lowest strength):

- Cover soil (internal shear strength, just above the geosynthetics)
- the cover soil/geocomposite drainage layer interface
- the geocomposite drainage layer/LLDPE textured geomembrane interface
- the LLDPE textured geomembrane/CCR material interface
- CCR (internal shear strength, just below the geosynthetics)

The interface strengths of the various materials in the cap system were evaluated to compare to the minimum acceptable strengths plotted in Section 4.

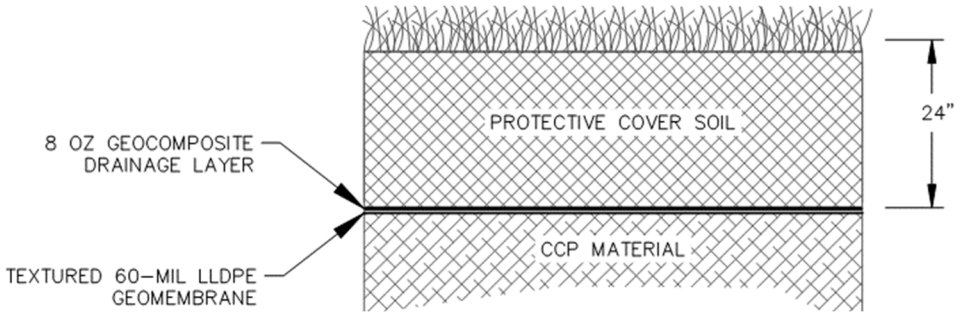

Figure 3. Cap System Constructed at the Sluice Trench and Ballfield East of the Sluice Trench (AECOM 2019)

3.2. COVER SOIL PARAMETERS

Values for the drained shear strength, moist unit weight, and saturated unit weight of the cover soil are required to perform the veneer stability analyses. Estimated parameters for the cover soil are summarized in Table 3.

The cover soil was sourced from the ”I-40 borrow area” and generally classified as fat clay with sand (CH), as detailed in the construction certification report for the closure of the unit in 2016 (AECOM 2016). It is assumed that similar material was used for the cover soil in the 2019 East Dike Area Closure.

Moist and saturated unit weights for the cover soil were estimated from available lab testing results. See Section 4.1 of the SAR for additional details.

For the veneer stability analysis, the drained shear strength parameters for the cover soil were estimated based on typical values from NAVFAC (1986) (see Figure 3 in Appendix D). Additionally, it is assumed that the Cover Material and CCR underlying the cap have no adhesion.

Table 3. Cover Soil Parameter Summary

Parameter	Value
Drained Friction Angle	19˚
Drained Cohesion	0 psf
Moist Unit Weight	120 pcf
Saturated Unit Weight	121 pcf

3.3. GEOSYNTHETIC PARAMETERS

The cover system constructed at the Sluice Trench and Ballfield East of the Sluice Trench was not evaluated for veneer strength prior to construction, likely due to the unit being relatively flat. It is assumed that the geocomposite/geomembrane interface is the weakest (i.e., most critical) of the above listed interfaces within the cap system.

Per the construction certification report for the closure of the East Dike, the geomembrane and geocomposite products used in the cap were the Agru 60-mil Microspike LLDPE and SKAPS Transnet HDPE Geocomposite with TN 330 Geonet (8 oz/yd^2) (AECOM 2019). No product-specific strength data was available in the construction report. In order to estimate the interface strength of the geocomposite/geomembrane interface, a literature review was conducted.

To estimate the geocomposite/geomembrane interface shear strength, a selection of studies was used to estimate the interface strength (Pavanello *et al.* 2018, Akpinar and Benson 2005, Stark *et al.* 1996, Bacas *et al.* 2015). Some of the geosynthetic interfaces evaluated in these papers were comparable to the interfaces within the cap system at KIF. The manufacture sheets for the installed geomembrane and geocomposite were used to compare the material type, asperity height, density, and thickness of the installed materials to those evaluated in the referenced studies. Based on the manufacture sheet, the Agru 60-mil LLDPE geomembrane has a nominal thickness of 1.5 mm and an asperity height of 0.51 mm. The SKAPS Transnet HDPE Geocomposite with TN 330 Geonet is composed of a nonwoven geotextile heat bonded with the geonet and geotextile with a mass per unit area of 8 oz/yd^2, or 270 g/m^2.

- Pavanello *et al.* (2018) evaluated the static interface angle of textured HDPE geomembrane and nonwoven geotextile as part of their investigation of the dynamic friction and seismic performance of various geosynthetic interfaces. The thickness of the textured geomembrane evaluated was 1.5

mm and the nonwoven geotextile evaluated had a mass per unit area of 300 g/m^2. The average, static interface friction angle for the geotextile/geomembrane interface was measured to be about 24˚.

- Akpinar and Benson (2005) evaluated the shear strength of interfaces between nonwoven geotextiles and HDPE geomembranes, including a textured geomembrane, as part of their investigation. The textured geomembrane evaluated had an asperity height of 0.25 mm, and the geotextile evaluated has a mass per unit area of 270 g/m^2. Although asperity height of the geomembrane evaluated is approximately half of height for the installed geomembrane, the system as a whole compares well to the interface within the cap system at the Sluice Trench and Ballfield East of the Sluice Trench. The interface friction angle for the geotextile/geomembrane interface was measured to be approximately 26˚.

- Stark *et al.* (1996) evaluated multiple geosynthetic interfaces, including a co-extruded geomembrane and geocomposite composed of nonwoven geotextile and thermally bonded geonet. The geomembrane evaluated had an asperity height of 0.45 mm and nominal thickness of 1.5 mm. The mass per unit area of the geocomposite evaluated was 270 g/m^2. It was found that the presence of the geonet did not significantly increase the interface shear resistance compared to the textured geomembrane/nonwoven geotextile interface, and the interface friction angle was estimated to be 30˚.

- Bacas *et al.* (2015) evaluated multiple geomembrane/geocomposite interfaces as part of their investigation of frictional behavior of typical geosynthetic interfaces. The interface evaluated most similar to the geocomposite/geomembrane interface within the cap system is a textured geomembrane, with an asperity height of 0.5mm, and a geocomposite composed of nonwoven 200 and 300 g/m^2 geotextile thermally bonded to the geonet. The 300 g/m^2 geotextile face of the geocomposite was placed on top of the geomembrane for the evaluation of the interface friction. The interface friction angle for this interface was found to be 16˚.

Considering all of the above published parameters, the interface friction suggested by Bacas *et al.* of 16˚ was selected as representative for the interface friction of the geomembrane/geocomposite interface within the cap system at KIF. This value was selected because the materials within the study were similar to those used in the cap system, and that this value represented the most conservative choice, as Pavanello *et al.* (2018), Akpinar and Benson (2005) and Stark *et al.* (1996) indicate the value may be much higher.

4. ANALYSIS RESULTS

The calculations for each design condition are presented at the end of this appendix.

4.1. STATIC CASE

The result from the drained, static case is plotted in Figure 4. The interface friction angle/adhesion combinations required to meet the target factor of safety (Table 1) are plotted. The plotted point represents the minimum interface strength within the cap system (applicable to all potential interfaces along the bottom of the cover system). Applying the minimum interface strength within the cap system, the static, drained case has a factor of safety of 1.8.

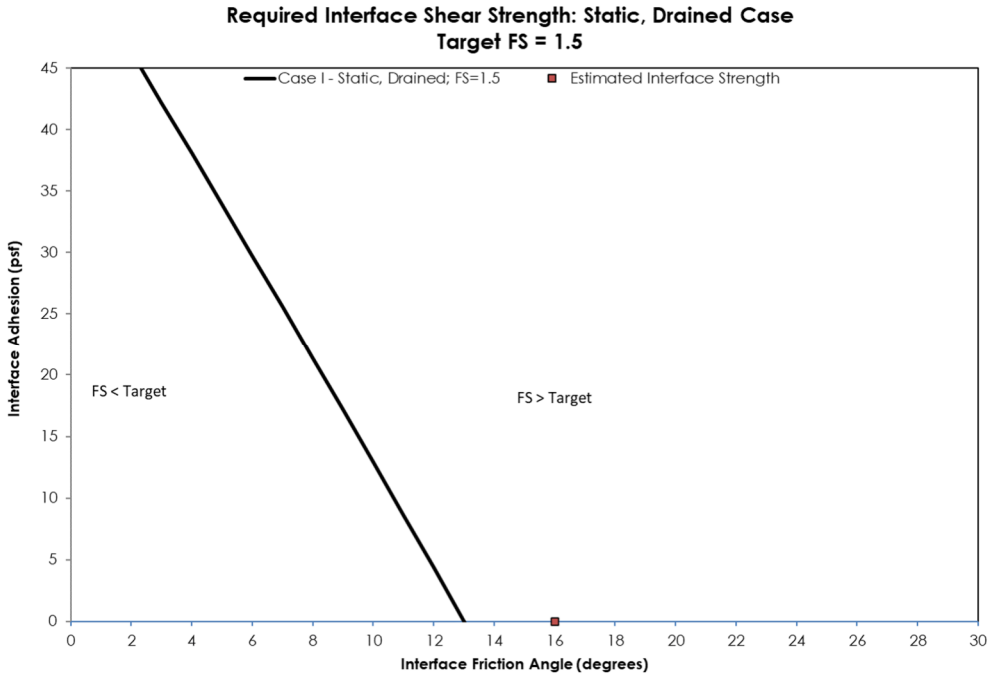

Figure 4. Estimated Interface Strength of Cover System and Adhesion/Friction Angle Combinations for Target Factor of Safety for Static, Drained Case

APPENDIX D – A REFERENCE FOR CHARACTERIZING THE ENGINEERING PROPERTIES OF SOILS

A Reference for Characterizing the Engineering Properties of Soils

Purpose:

- This document provides focused background discussion, typical values, empirical correlations, and guidance for selecting engineering soil properties.

Developed by: Stantec Consulting Services Inc.	
Prepared by: Alan Rauch	*Reviewed by:* Jeff Dingrando

A Reference for Characterizing the Engineering Properties of Soils

1. Introduction

This document provides focused background discussion, typical values, empirical correlations, and guidance for selecting engineering soil properties. The emphasis is on the soil parameters needed for slope stability analyses. The measurement and selection of soil properties is a broad subject, and this document does not provide a comprehensive review. Good textbook treatments are provided in Lambe and Whitman (1969), Holtz and Kovacs (1981), Terzaghi et al. (1996), and Duncan et al. (2014).

It is impossible to anticipate the conditions that will be encountered at a particular site or project. The engineering team must select the appropriate methods for characterizing each soil, based on the available data, specific characteristics of the material, geologic setting, application of the parameter in the analysis, and professional judgment.

2. Density Parameters

The unit weight of a given soil varies with water content, with different values in a deposit above or below the water table. Unit weights for various moisture conditions can be computed as follows:

Dry unit weight $$\gamma_d = \frac{G_s}{1+e}\,\gamma_w$$ **Equation 1**

Moist unit weight $$\gamma_m = \gamma_d(1+w)$$ **Equation 2**

Saturated unit weight $$\gamma_{sat} = \frac{G_s + e}{1+e}\,\gamma_w$$ **Equation 3**

where G_s is the specific gravity of the solids, e is the void ratio, w is the gravimetric moisture content, and γ_w is the unit weight of water (62.4 pcf). Specific gravity is typically about 2.65 for sands, and about 2.7 for clays.

The gravimetric water content (w) is the ratio of the water weight over dry weight of solids in the soil. The volumetric water content (θ), defined as the ratio of water volume over total soil volume, is used in some analyses. These two measures of moisture content can be related:

$$\theta = \frac{G_s\, w}{1+e} = \frac{S\, e}{1+e} = S\, n$$ **Equation 4**

where e is void ratio, S is saturation, and n is porosity. In a saturated soil (S = 100%), the volumetric water content is equal to the porosity.

Direct measurements of density properties are obtained from field and laboratory testing. When direct measurements are not available, these properties can be estimated using typical values for similar materials, such as those tabulated in Figure 1 through Figure 3. In granular soils, unit weights can be estimated based on penetration resistance, which can be correlated to relative density (see Figure 19).

	Density (Mg/m³)†

Notes:

1. All properties are for condition of "Standard Proctor" maximum density, except values of k and CBR which are for "modified Proctor" maximum density.
2. Typical stength characteristics are for effective strength envelopes and are obtained from USBR data.
3. Compression values are for vertical loading with complete lateral confinement.
4. (>) indicates that typical property is greater than the value shown.
   (..) indicates insufficient data available for an estimate.

3. Hydraulic Conductivity

This discussion relates to the seepage of water through soil per Darcy's law, wherein the seepage flow rate is proportional to the hydraulic gradient. The key soil parameter is the hydraulic conductivity (k); here, the generic term "permeability" is assumed to be synonymous with hydraulic conductivity.

Hydraulic conductivity varies over an extremely wide range for different soils, and the permeability of a large soil mass is difficult to determine with precision. Measurements made with discrete soil samples will fail to capture the influence of macro seepage features (fissures, discontinuities, inclusions, thin beds of different material, etc.) that may have a major impact on seepage through the soil mass. More representative values can sometimes be obtained through field testing, but such tests are expensive and difficult to interpret. The characterization of soil permeability parameters requires significant engineering judgment.

Seepage analyses may be performed to characterize the distribution of pore water pressures in an earth slope, without regard to seepage flow rates. For this type of problem, the relative permeabilities between the various soil strata and/or the ratio of horizontal to vertical permeability (anisotropy ratio) within a given soil zone, are more important to the model solution than the absolute permeability of any particular soil. Thinking about the flownet for a uniform, isotropic seepage problem, the head (or pressure) at any location is independent of the hydraulic conductivity. Also, if the permeability in one material is more than about two orders of magnitude higher than the adjacent soil, then the first will act like a drain and can be modeled as a boundary condition.

The engineer should consider these issues in selecting appropriate permeability parameters for a particular analysis, recognizing that the needed solution may not be sensitive to the permeability of some materials. Permeability estimates, based on typical values for similar soils, are often sufficient and appropriate for developing a reasonable seepage model. Testing and evaluation should be concentrated on the soil zones that are critical to the problem.

3.1. Saturated Soil Permeability

The tables and charts provided below are useful when estimating hydraulic conductivity for saturated soils, or when checking the validity of permeability measurements. The charts in Figure 4 classify soil behavior in terms of permeability ranges, while data for common soils and embankment materials are provided in Figure 3 and Figure 5 though Figure 7.

The hydraulic conductivity of clean, loose, uniform sands can be estimated using Hazen's empirical equation:

$$k \approx C\ (D_{10})^2 \qquad \textbf{Equation 5}$$

where k is the hydraulic conductivity (cm/sec), D_{10} (mm) is the effective grain size (10% of soil particles are smaller than D_{10}), and C is an empirical constant that typically varies between 0.8 and 1.2. This empirical correlation illustrates that permeability is strongly affected by the finer particles in a soil. However, Hazen's equation was developed for filter sands, and is thus limited in applicability to loose, uniform sands with less than 5% fines.

Hydraulic conductivity is also affected by how densely the soil particles are packed together. The change in permeability with the change in density, for a particular soil, can be estimated using:

$$k_1\left(\frac{e_2^3}{1+e_2}\right) = k_2\left(\frac{e_1^3}{1+e_1}\right) \qquad \textbf{Equation 6}$$

where k_1 is the permeability at a void ratio of e_1, and k_2 is the permeability of the same soil at a void ratio of e_2. Equation 6 is based on the Kozeny-Carman equation (Lambe and Whitman 1969).

In the laboratory, hydraulic conductivity can be measured directly from constant head permeability tests (preferred for soils with $k > 10^{-3}$ cm/sec) or falling head permeability tests (preferred for soils with $k < 10^{-5}$ cm/sec). The permeability of fine-grained soils can also be determined from the results of one-dimensional consolidation tests. The accuracy of laboratory permeability measurements is limited, in all cases, by how well the test specimen represents the in situ soil deposit.

In the field, hydraulic conductivity can be measured with borehole or well infiltration (slug) tests, with variations of constant head, falling head, and pumping. Large-scale aquifer pumping tests, with arrays of piezometer instrumentation, can also be used to characterize the permeability characteristics of large soil masses. Double ring infiltrometer tests are commonly used to measure vertical permeability on soil liners. Further discussion of all available test methods is beyond the scope of this document.

3.2. Permeability from Slug Tests

Hydraulic conductivity parameters can be determined from slug tests in screened wells or piezometers. In the field, water is either poured into or removed from the well, causing a nearly instantaneous increase or decrease in the water level. The water levels are then recorded at regular intervals until returning to the initial static level. The Bouwer-Rice solution is then fit to this data to estimate the saturated permeability, for horizontal seepage in the soil or rock strata surrounding the screened interval.

The Bouwer-Rice solution (Bouwer and Rice 1976; Bouwer 1989) for estimating the coefficient of saturated hydraulic conductivity assumes a volume of water is instantaneously removed from a well and the return of the water level is measured. The method is based on a solution of the Thiem equation for steady-state, radial water flow to a well (see Figure 8):

$$Q = 2\pi \cdot k \cdot L_e \frac{y}{\ln\left(\frac{R_e}{r_w}\right)}$$ **Equation 7**

where: Q = volumetric flow rate
k = coefficient of saturated hydraulic conductivity
L_e = length of open section of the well (screened interval)
y = vertical distance between water level in the well and static water level of groundwater aquifer
R_e = effective radial distance over which y is dissipated
r_w= radial distance of the undisturbed portion of the aquifer

The change in water elevation within a well over a change in time is:

$$\frac{dy}{dt} = \frac{-Q}{\pi r_c^2}$$ **Equation 8**

where r_c is the inside radius of the well casing if above the open portion of the well (the porosity of the surrounding material may need to be considered if the water level is changing in the open portion of the well)

Bouwer and Rice assumed that the draw-down of the water table around the well is negligible, flow in the vadose (unsaturated) zone can be ignored, head losses are negligible, and the aquifer is both homogeneous and isotropic. Bouwer and Rice combined the two equations and solved for the coefficient of saturated hydraulic conductivity assuming boundary conditions of y_o at t = 0.0 and y_t at t:

$$k = \frac{r_c^2 \cdot \ln\left(\frac{R_e}{r_w}\right)}{2 \cdot L} \cdot \frac{1}{t} \cdot \ln\frac{y_o}{y_t}$$ **Equation 9**

The effective radial distance over which y is dissipated (R_e) was determined by Bouwer and Rice for different geometries based on an electrical resistance network analog. Thus, the value must be determined from their literature (Bouwer and Rice, 1976). This form of the equation allows k to be calculated from the rise in water level after suddenly removing a slug of water from the well. The term $\frac{1}{t} \cdot \ln\frac{y_o}{y_t}$ may be determined from a best fit linear regression of field data plotted as ln(y) versus t.

Bouwer (1989) explained the applicability of using the method to determine the coefficient of saturated hydraulic conductivity from a slug test where water is added to the well.

3.3. Permeability from CPT Dissipation Tests

In situ soil permeability can be estimated from pore pressure dissipation data acquired during cone penetration testing (CPT). When the piezocone probe is stopped, at selected depths or intervals in a saturated deposit, the excess pore water pressures induced by pushing the cone will begin to dissipate. Based on consolidation theory, the rate of pore pressure dissipation can be related to the lateral hydraulic conductivity of the soil surrounding the probe. The method presented below assumes the penetration pore pressures are measured immediately behind the conical tip, at the "u_2" location.

The horizontal permeability (k_h) of a soil is determined from a CPT dissipation test as follows:

(1) Halt advancement of the piezocone and record the soil water pore pressures (u_t) as a function of time (t).

(2) From the data, determine the initial pore pressure (u_i) measured when the piezocone was halted, at t = 0.0.

(3) Estimate the static pore pressure (u_o) at the test location before penetration of the cone. This may be determined from knowledge of the ground water table in relation to the depth of the CPT probe, piezometric readings, or data from piezocone tests in adjacent sand layers.

(4) Compute the normalized excess pore pressure (U) for each measurement of u_t:

$$U = \frac{u_t - u_o}{u_i - u_o} \qquad \textbf{Equation 10}$$

(5) Plot the normalized excess pore pressure dissipation as a function of time, using a log scale for the time axis.

(6) From the plot of data, determine the measured time for 50% pore pressure dissipation (t_{50}, measured at U = 0.5).

(7) Alternatively, t_{50} may be determined from a square root of time plot, using the graphical construction technique commonly used to interpret soil consolidation test data.

(8) The coefficient of saturated, horizontal hydraulic conductivity can then be estimated using either of the charts in Figure 9 (note the difference in time units between the two charts).

The resulting estimates of soil permeability are only approximate and subject to significant uncertainty (Lunne et al. 1997).

3.4. Anisotropic Permeability

Most natural soils and embankment materials are anisotropic, typically with horizontal stratification due to horizontal bedding in natural deposits or the construction of fills in horizontal lifts. This usually results in a horizontal permeability (k_h) greater than the vertical permeability (k_v). Anisotropic permeability is characterized with the ratio of k_h/k_v (Note: SEEP/W uses the inverse ratio of k_v/k_h).

The magnitude of k_h/k_v is an important parameter to consider in a seepage analysis, but can be difficult to characterize. Vertical permeability is usually measured in laboratory tests, consistent with the orientation of borehole samples. Laboratory testing is less effective for measuring horizontal permeability, due to the difficulty of obtaining representative samples suitable for such tests. Field tests, including slug tests in screened wells (Section 3.2) and CPT dissipation tests (Section 3.3), induce mostly radial seepage; horizontal permeability is inferred, but some vertical seepage will occur. There are limitations associated with each of these measurements. The anisotropy of the materials is not measured directly, thus, the value of k_h/k_v must be approximated by combining different test results and considering knowledge of the subsurface stratigraphy.

The U.S. Army Corps of Engineers suggests that values of $k_h/k_v = 1, 10, 25, 100$ should be considered for parametric evaluations of underseepage (EM 1110-2-1901, USACE 1986). Typical ranges of k_h/k_v for various natural soils and embankment fills, as suggested by the U.S. Bureau of Reclamation (USBR 2011b), are listed in Figure 6 and Figure 7.

Selection of an appropriate value of k_h/k_v should consider the depositional environment for the material. Wind-blown soils (dune sands, loess) are relatively uniform, with k_h/k_v values in the range of 0.2 to 2. Residual soils may also have low k_h/k_v, depending on the structure of the parent rock. Deposition in water (alluvial, fluvial, and lacustrine environments) usually leads to highly stratified and variable soil deposits, with relatively high k_h/k_v. These classes of soils may have $k_h/k_v > 100$ (USBR 2011b). Anisotropy in bedrock is generally controlled by the degree of stratification and jointing.

The USBR (2011b) indicates that compacted embankment soils typically have k_h/k_v ratios in the range of 2 to 10. Older dams (built in early 20th century) and hydraulic fill dams may have k_h/k_v up to 50, due to older construction procedures that did not adequately scarify and mix the surface of each compacted soil lift. Coarse grained embankment zones, including drains, filters, and rockfill shells, can be assumed to have $k_h/k_v = 1$.

Degree of Permeability	Hydraulic Conductivity (cm/sec)
High	Greater than 10^{-1}
Medium	10^{-1} to 10^{-3}
Low	10^{-3} to 10^{-5}
Very Low	10^{-5} to 10^{-7}
Practically Impermeable	Less than 10^{-7}

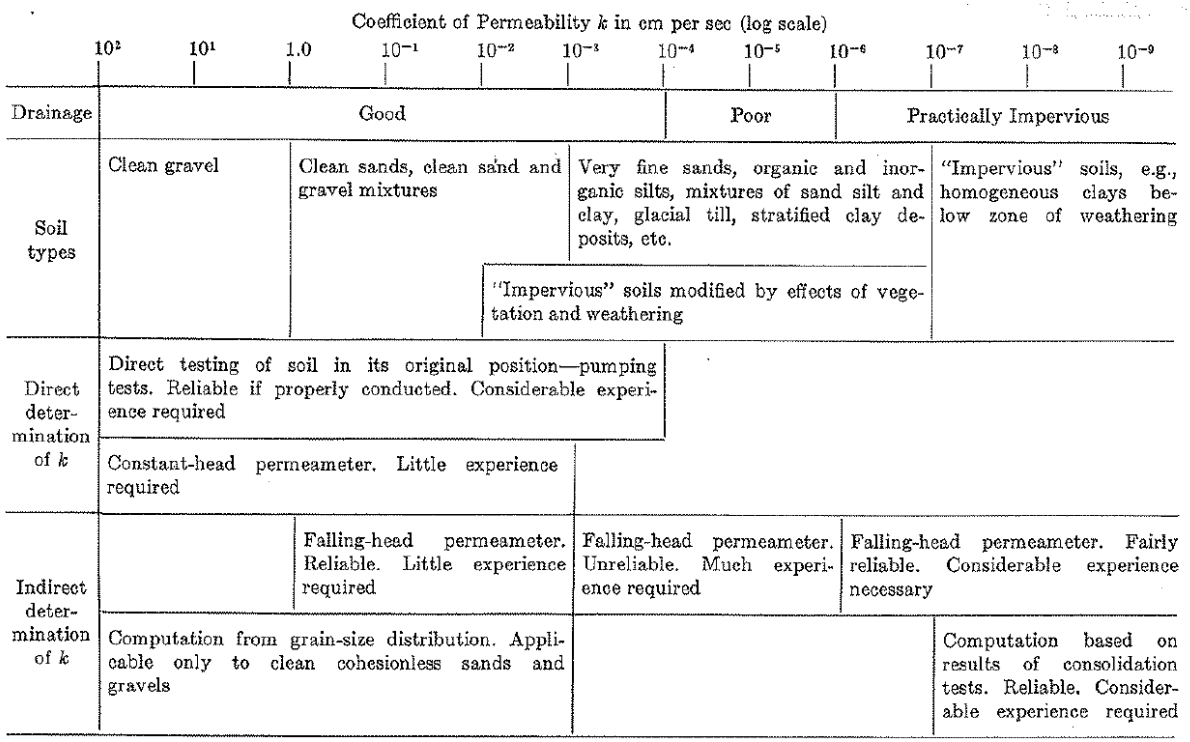

Figure 4. Hydraulic conductivity and classification of soils (from Terzaghi and Peck 1967).

Formation	Value of k (cm/sec)
River deposits	
Rhone at Genissiat	Up to 0.40
Small streams, eastern Alps	0.02–0.16
Missouri	0.02–0.20
Mississippi	0.02–0.12
Glacial deposits	
Outwash plains	0.05–2.00
Esker, Westfield, Mass.	0.01–0.13
Delta, Chicopee, Mass.	0.0001–0.015

3.5. Seepage in Unsaturated Soils

For unconfined seepage through an embankment, SEEP/W locates the phreatic line or water table (where the pressure head is zero) using an iterative process (GEO-SLOPE

2010). To find a rational solution, the software models the reduction in hydraulic conductivity with decreasing degrees of saturation (increasing matric suction) using the soil-water characteristic curve and hydraulic conductivity function described here.

These models are defined in terms of the *volumetric* water content (θ), which is related to the gravimetric water content (w) per Equation 4. Suction pore pressures are quantified in terms of the matric suction, which is the difference between the pore air pressure and the water pressure in an unsaturated soil (Fredlund and Rahardjo 1993).

3.5.1. Soil-Water Characteristic Curve

The Soil-Water Characteristic Curve (SWCC) represents the amount of water within the soil structure at various applied suctions (Fredlund and Rahardjo 1993). Figure 10 shows a typical soil-water characteristic curve, also known as a volumetric water content curve, plotted over a range of pore water pressure (negative to positive). Soils exhibit hysteresis in this relationship for wetting and drying, but only the SWCC curve for drainage (desorption) is discussed here. The SWCC is characterized by four parameters: the air entry pressure (described using a curve-fitting parameter α), the slope of the function for changes in pore water pressure (described using a curve-fitting parameter n), the residual volumetric water content (θ_r), and the saturated volumetric moisture content (θ_s).

The air entry value (AEV), represents the matric suction pressure where a saturated soil begins to de-saturate (where air enters the pores). At pore pressures above the AEV, the water within the soil mass can be removed by compressing the sample; therefore, the slope of the curve under positive pore pressures is equal to the coefficient of volume compressibility (M_v) for one-dimensional consolidation (GEO-SLOPE 2010). Once the pore water pressure falls below the AEV, water cannot be compressed out of the sample; rather, water can only be removed from the voids by applying suction pressure. Therefore, the SWCC for pressures below the AEV indicates how much water can be removed as the matric suction is increased, until the residual water content is reached. The residual volumetric water content (θ_r) occurs where further increases in matric suction do not result in significant changes in water content (Fredlund and Rahardjo 1993). The saturated volumetric moisture content (θ_s), defines the intersection of the SWCC and the x-axis (i.e. pore water pressure equals zero).

Within SEEP/W, the user can define the SWCC using direct measurements from laboratory tests, the built-in library of curves based on material classification, or one of the models proposed by Aubertin at al. (2003), van Genuchten (1980), and Fredlund and Xing (1994).

When available, laboratory test data should be used to define the soil-water characteristic curve in the SEEP/W model. Five standardized test methods, which vary in applicability based on fines content and pressure ranges, are presented in ASTM D6836. Method C, for finer soils and intermediate suctions (100 to 1000 kPa), can be used for most soil samples. When using laboratory data, it may be necessary to augment the data for the higher and lower suction pressures not tested. The Aubertin,

van Genuchten, or SEEP/W soil type models can be used to develop a standard curve shape, which can then be modified to fit the available laboratory data.

In the absence of laboratory testing, the following methods can be used to develop the SWCC:

- The "Modified Kovacs" method (Aubertin et al. 2003) develops the curve using standard laboratory test data such as grain size distribution, Atterberg limits (if applicable), and the saturated volumetric water content.

- SWCC parameters can be estimated from empirical relationships using soil index properties or using typical published values. Figure 11 provides some tables of typical values. Typical van Genuchten model parameters (α, n) including residual (θ_r) and saturated (θ_s) water contents are compiled from the UNSODA database (Leij et al., 1996). N indicates the number of soils or samples of a given textural class from which the mean values are compiled. During desorption, large pores drain more freely than smaller pores. Materials with larger particles and larger pores (e.g., sand and gravel) will retain less water under higher suction pressures. SWCC for coarse soils are difficult to measure in the laboratory. Figure 12 provides published values of curve fitting parameters for coarse soils and illustrates the corresponding SWCC.

- The SWCC can be approximated by choosing one of the functions developed by GEO-SLOPE for a given soil texture, which are based on functions taken from published literature (GEO-SLOPE 2010). The six available models are based on the soil type: Clay, Silty Clay, Silt, Silty Sand, Sand, and Gravel (shown in Figure 13). The models shown are for illustration purposes only and are dependent on the saturated volumetric water content.

3.5.2. Hydraulic Conductivity Function

When the soil is saturated, water flows through the pores easily, but as the water content decreases, the hydraulic conductivity drops rapidly as the water in the soil pores is no longer contiguous. Hence, the hydraulic conductivity of an unsaturated soil is dependent on the volumetric water content. SEEP/W estimates the hydraulic conductivity of unsaturated soils by using the SWCC, the suction pressure within the soil, and the saturated hydraulic conductivity of the soil.

A Hydraulic Conductivity Function can be derived to estimate the hydraulic conductivity over a range of suction pressures. The two methods available in SEEP/W to derive the Hydraulic Conductivity Function are from Fredlund and Xing (1994) and van Genuchten (1980). The saturated hydraulic conductivity (Section 3.1) and the SWCC are required to create the hydraulic conductivity curve. Figure 14 shows an example Hydraulic Conductivity Function for various saturated hydraulic conductivity values.

4. Small-Strain Shear Stiffness

4.1. Elastic Stiffness and Wave Velocity

In an elastic medium, the velocity of a stress wave is equal to the square root of the ratio of elastic modulus over mass density. For a shear wave, the velocity (V_s) is related to the shear modulus (G). The shear response of soils is nonlinear, such that the shear modulus declines at increasing shear strains (softening). The elastic response is limited to very small strains, where the shear modulus is maximum. Hence, the maximum shear modulus (G_{max}) in a soil at small strains is proportional to the square of the shear wave velocity in that soil:

$$G_{max} = \rho \, V_s^2 \qquad \textbf{Equation 11}$$

where ρ is the mass density (total unit weight divided by acceleration due to gravity, 32 ft/sec^2).

Shear wave velocities can be measured in multiple ways. Resonant column or cyclic triaxial testing can be used in the laboratory, but in situ field measurements are preferred. Field techniques include cross-hole testing in boreholes, down-hole testing during cone penetration tests, seismic refraction methods, and other surface and downhole geophysical methods. Direct, field measurements of shear wave velocity are the best method for characterizing the small-strain shear modulus of a soil mass.

When shear wave measurements are not available, G_{max} can be estimated using various empirical correlations. Such correlations have been published by Ishihara (1996) and Kramer (1996). A few select correlations are presented below.

4.2. G_{max} Correlations Based on Void Ratio

Seed and Idriss (1970) proposed this correlation for sand:

$$G_{max} = 1{,}000 \, K_{2,max} \, (\sigma'_m)^{0.5} \qquad \textbf{Equation 12}$$

where G_{max} is the small-strain shear modulus (psf) and σ'_m is the mean effective stress (psf). The correlation factor $K_{2,max}$ in Equation 12 is estimated based on the void ratio (e) or relative density (D_r) of the sand:

e	$K_{2,max}$	D_r (%)	$K_{2,max}$
0.4	70	30	34
0.5	60	40	40
0.6	51	45	43
0.7	44	60	52
0.8	39	75	59
0.9	34	90	70

Another relationship, more generally applicable to various soil types, was proposed by Hardin (1978):

$$\frac{G_{max}}{P_a} = \frac{625}{0.3 + 0.7\,e^2}\,OCR^k\left(\frac{\sigma'_m}{P_a}\right)^{0.5} \qquad \textbf{Equation 13}$$

where e is the void ratio and OCR is the overconsolidation ratio. P_a is one atmospheric pressure (101.3 kPa or 2,116 psf), in the same units as G_{max} and the mean effective stress (σ'_m). The exponent k in Equation 13 is related to plasticity index (PI), and can be interpolated between these values (Hardin and Drnevich 1972):

PI	k
0	0.00
20	0.18
40	0.30
60	0.41
80	0.48
≥ 100	0.50

In these correlations, the mean effective stress is defined as

$$\sigma'_m = \frac{1}{3}(\sigma'_1 + \sigma'_2 + \sigma'_3) \approx \frac{2}{3}\,\sigma'_v \qquad \textbf{Equation 14}$$

where σ'_1, σ'_2, and σ'_3 are the principal effective stresses. In most applications, assuming at-rest conditions and $K_o = 0.5$ will provide sufficient accuracy. The mean stress is then about two-thirds of the vertical effective stress, as indicated in Equation 14.

4.3. G_{max} Correlations Based on Penetration Resistance

The value of G_{max} may be estimated on the basis of correlations with in situ penetration resistance. For sand, Seed et al. (1986) suggest:

$$G_{max} = 20{,}000\,(N_1)_{60}^{0.333}\,(\sigma'_m)^{0.5} \qquad \textbf{Equation 15}$$

where G_{max} is the small-strain shear modulus (psf), σ'_m is the mean effective stress (psf), and $(N_1)_{60}$ is the normalized, corrected Standard Penetration Test (SPT) blowcount.

When cone penetration test (CPT) data is available, G_{max} in sands may be estimated using (Rix and Stokoe 1991):

$$G_{max} = 1{,}634\,(q_c)^{0.250}\,(\sigma'_v)^{0.375} \qquad \textbf{Equation 16}$$

where G_{max} is the small-strain shear modulus, q_c is the CPT tip resistance, and σ'_v is the vertical effective stress, all expressed in units of kPa. In clays, G_{max} may be estimated from CPT data using (Mayne and Rix 1993):

$$G_{max} = 406\,(q_c)^{0.695}\,(e)^{-1.130} \qquad \textbf{Equation 17}$$

G_{max} and σ'_v are expressed in units of kPa, and e is initial void ratio of the soil.

4.4. G_{max} Correlations Based on Site-Specific Data

Maximum shear modulus (G_{max}) typically varies with effective stress level and can be generally defined as follows:

$$G_{max} = G_o \left(\frac{\sigma'_m}{P_a}\right)^{0.5} \qquad \textbf{Equation 18}$$

Shear wave velocity measurements obtained from field or lab testing are often available over a limited range of effective stresses that may not encompass the range of stresses of interest in ground response analyses. In this scenario, site-specific data can be extrapolated to a broader stress range by selecting a representative G_o value for a given material. The representative G_o value should be selected such that shear wave velocities calculated using Equation 18 and Equation 11 match field or lab measurements reasonably well over the stress range where data is available. In effect, this creates a site-specific empirical correlation. An example correlation and the associated field data are shown in Figure 15.

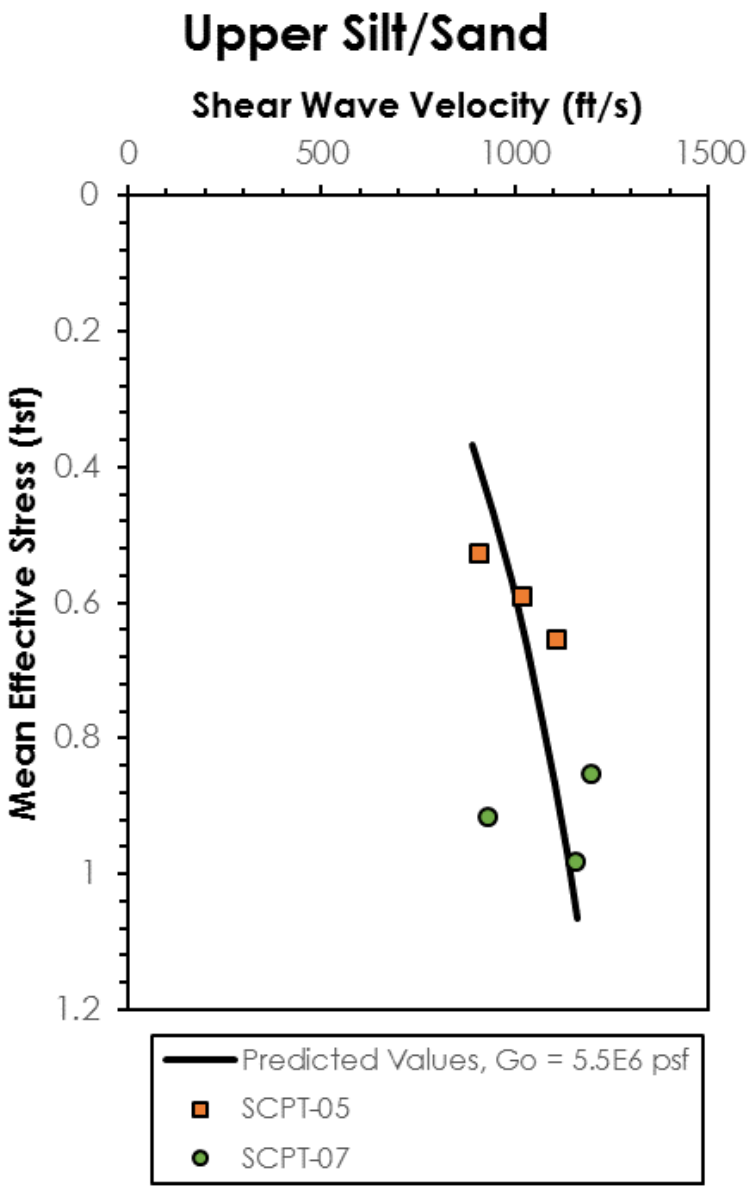

Figure 15. Example site-specific empirical correlation for shear wave velocity

5. Strength Parameters from Laboratory Test Data

Soil strengths can be determined from the results of laboratory tests, including direct shear, triaxial compression, triaxial extension, and direct simple shear tests. From the measured soil response to loading, the "failure" stresses are plotted and a Mohr-Coulomb failure envelope is fit to the data. In geotechnical engineering practice, soil shear strengths (S) are commonly characterized in terms of the intercept (c) and slope (tan ϕ) of the Mohr-Coulomb envelope:

$$S = c + \sigma \tan\phi \qquad \textbf{Equation 19}$$

5.1. Definition of Failure

Selecting the point of failure in a laboratory test record requires some engineering judgment. Criteria that are commonly used to define "failure" include:

- The point of maximum or peak applied shear stress.
- The shearing resistance at some arbitrary, limiting strain level (usually 15% axial strain in triaxial compression).
- The maximum principal effective stress ratio (maximum value of σ'_1/σ'_3); sometimes identified as the point of maximum obliquity, this stress condition is one where the slope of a failure envelope through the origin of stress has a maximum slope (maximum ϕ for c = 0).
- The residual shearing resistance at large strain.

When selecting the point of failure in a particular test, the following guidelines should be followed:

- When considering data from drained (CD) tests, failure can be defined as the point of maximum shear stress or 15% axial strain, whichever occurs first. In a drained triaxial test, the maximum value of σ'_1/σ'_3 occurs at the point of maximum applied shear stress, so both criteria will give the same result.

- In evaluating effective stress parameters (c' and ϕ') from CU test data, failure should be assumed at the maximum principal effective stress ratio.

- When analyzing data from undrained (UU or CU) laboratory tests, the peak axial stress should be assumed to represent failure when determining undrained strength parameters (c and ϕ). If the test data does not exhibit a peak stress prior to 15% axial strain (for triaxial testing), then the stresses at 15% strain should be used as failure.

Note that the drained and undrained failure stresses will occur at different points in a given CU test, due to the different definitions of failure used in each case.

5.2. Fitting Strength Envelopes

Values of c and ϕ are determined from a straight line, tangent envelope fit to Mohr's circles representing failure stresses. When working with data from multiple laboratory tests, fitting of the failure envelope may be facilitated by plotting the failure points on a "p-q plot", where:

$$p = \frac{\sigma_1 + \sigma_3}{2} \qquad \textbf{Equation 20}$$

$$q = \frac{\sigma_1 - \sigma_3}{2} \qquad \textbf{Equation 21}$$

A "best-fit" line through the p-q failure points (identified as the K_f line) will then have an intercept of "d" and a slope of "tan a". Equivalent Mohr-Coulomb parameters can then be computed as:

$$\sin\phi = \tan\alpha \qquad \textbf{Equation 22}$$

$$c = \frac{d}{\cos\phi} \qquad \textbf{Equation 23}$$

Equation 20 through Equation 23 can be used with either drained strengths (c' and ϕ') or undrained strengths (c_R and ϕ_R for R-envelopes).

Note that the Mohr-Coulomb failure model (Equation 19) corresponds to a linear increase in shearing resistance with higher normal stress. Actual failure envelopes for soils are curved, with significant curvature in the effective stress envelopes for granular soils over large pressure ranges and for overconsolidated clays. In practice, values of c and ϕ are determined for soils from straight line envelopes fit to specific ranges of stress.

In fitting strength parameters to multiple test results, the practice of the U.S. Army Corps of Engineers is to select design values of c' and ϕ' (or c and ϕ) so that data from about two-thirds of the tests are above the failure envelope (USACE 2003). This guidance can also be used in selecting design values of undrained shear strength (S_U) or c/p ratios; that is, about two-thirds of the measured strengths should be above the strength used in design.

6. Drained Strength Parameters for Static, Long Term Conditions

6.1. Basis

Excess (or deficient) pore water pressures, generated by changes in mean stress or shearing stress, will dissipate under static, long term conditions. Pore pressures within a soil can then be computed assuming hydrostatic conditions or from a solution for steady state seepage. As long as the distribution of pore pressure within the cross section can be quantified, effective stresses can be computed and the drained shear strength (S_d) of the soils can be determined from effective stress strength parameters (c' and ϕ'):

$$S_d = c' + \sigma' \tan \phi' \qquad \textbf{Equation 24}$$

6.2. Effective Stress Cohesion Intercept

Uncemented, granular soils exhibit no strength at zero effective stress ($\sigma' = 0$), corresponding to c' = 0. Over a wide pressure range, granular soils have a curved strength envelope. Fitting a straight line through segments of a curved failure envelope can result in c' > 0, but these values are applicable only for modeling the shear strength over the specified range of effective stress. In the case of unsaturated soils with fines, suction creates an apparent cohesion, but this component of strength is lost when the soil becomes saturated. In general, zero cohesion (c' = 0) should be assumed for uncemented, granular soils.

Normally consolidated, saturated clays also have no shear strength at zero effective stress. The drained, Mohr-Coulomb failure envelope for the peak strength of a normally consolidated clay will have c' = 0.

The peak strength envelope for an overconsolidated clay will exhibit drained cohesion. Below the effective preconsolidation pressure, the drained strength envelope for an overconsolidated clay is above the envelope for the normally consolidated condition. The overconsolidated, peak strength envelope is nonlinear, and curves toward the origin at very small effective stresses (Figure 16). Linear Mohr-Coulomb failure parameters (with c' > 0) can be fit to the curved strength envelope for overconsolidated soils; however, envelopes fit with c' > 0 will tend to overestimate the drained shearing resistance at shallow depths.

Moderately to heavily overconsolidated clays in the field are often fissured, especially at shallow depths. Because test specimens tend to be taken between the fissures, laboratory tests on smaller specimens tend to yield larger values of c', compared to tests on larger samples of such soils. For overconsolidated soils, c' determined from laboratory testing thus tends to be larger than the in situ cohesion of the soil mass, and thus potentially unconservative. In addition, cycles of shrinking (drying) and swelling (wetting) lead to softening and a loss of stress history over time along the fissures. Fully softened strengths (Section 6.3) with c' = 0 (Stark et al. 2005) are thus appropriate for characterizing the drained strength of stiff, fissured, overconsolidated clayey soils.

Fell et al. (2005) point out that measured values of drained cohesion may be adversely affected by potential shortcomings in the laboratory test results. For example, if tests are run at confining stresses higher than experienced in the field, a straight line fit through that data may overpredict the drained strength at lower effective stresses. If the soil sample is not completely saturated, or if the strain rate is too high to allow equilibration of pore pressures within the sample during the test, then the pore pressure data will not accurately reflect the pore pressures at failure. This will tend to shift the Mohr's failure stress circles, which can result in a misleading indication of drained cohesion.

At very large shear strains, clay particles will align with the slip surface and a residual shearing resistance is realized. Drained, residual strength envelopes (Figure 16) are independent of overconsolidation and have no cohesion (c' = 0). Residual strength parameters should be used when evaluating stability where sliding has previously occurred.

In the absence of particle cementation/bonding, long term (drained) shearing resistance related to c' > 0 may be unreliable. In routine geotechnical design practice, values of c' = 0 are usually assumed for both normally and overconsolidated saturated clays, and for uncemented granular soils. In the evaluation of long-term stability, Stark et al. (2005) recommend using zero effective stress cohesion (c' = 0) for soft to stiff clays, unless back-analysis of local case histories support a greater value. However, this recommendation considers the potential for softening of stiff clays, and may not apply to full depth (See Section 6.3).

Detailed testing and characterization of a particular soil, coupled with careful application of the fitted strength envelopes, are necessary where values of c' are used in a stability evaluation. Fell et al. (2005) recommend that design values of c' for peak strength should not exceed about 200 psf (or 20 psf for residual strengths) without definitive evidence for higher values.

When surficial soils have c' = 0, shallow sliding parallel to the ground surface will be the critical failure mechanism (lowest factor of safety) found in a slope stability analysis. This mode of failure, which might require periodic regrading and maintenance, is often considered to be less critical in a stability analysis.

Specific guidance on the selection of c' values is provided in Section 6.7.

6.3. Fully Softened Strengths of Overconsolidated Clays

In excavations and embankments, long-term failures may develop in overconsolidated clays at shear stresses below the peak drained strength. Seasonal moisture changes near the ground surface, or lateral stress relief in deep excavations, will cause fissures to open, swelling of the soil along the fissures, and the gradual loss of the beneficial effects of overconsolidation. Over time (years to decades), the peak strength of the overconsolidated soil mass may degrade to the lower strength of the soil when normally consolidated (Skempton 1970). "Fully softened strengths" (Figure 16) are appropriate for characterizing the drained strength of such soils. The understanding of this behavior, and the appropriate application of this concept for

design, is an evolving area within geotechnical engineering. Duncan et al. (2011) and VandenBerge et al. (2013) provide an overview of current geotechnical engineering practice, based on the outcomes of a 2011 industry workshop.

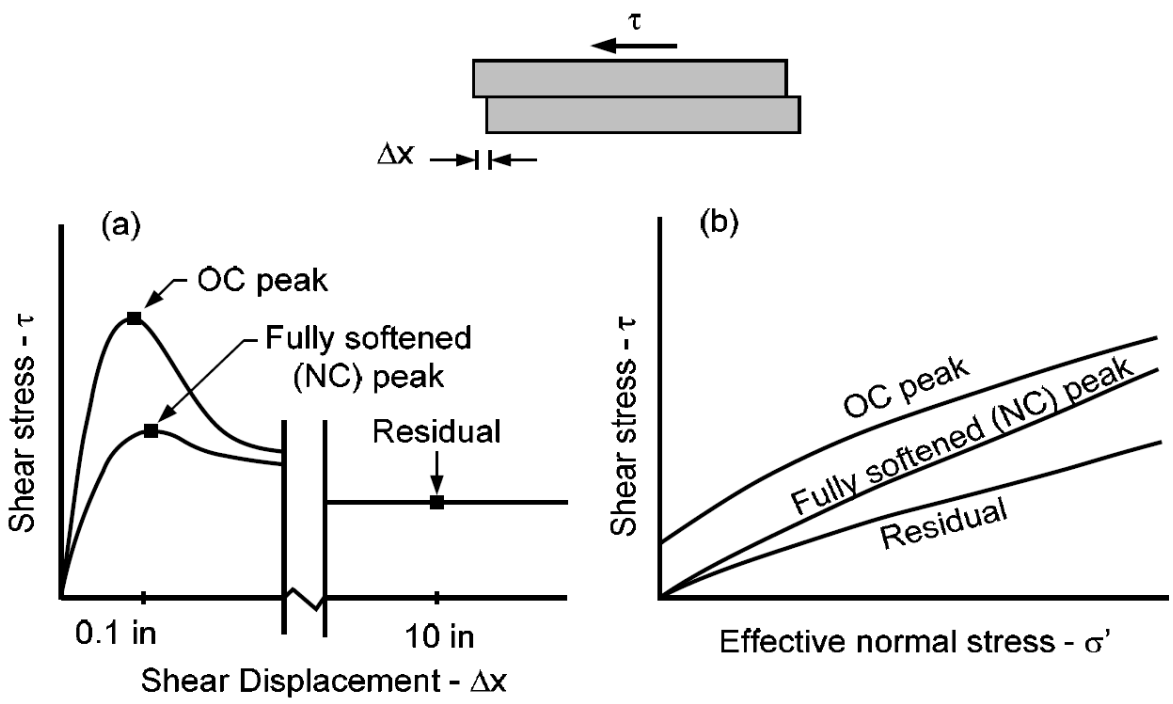

Figure 16. (a) Stress-displacement curves for overconsolidated and fully softened (normally consolidated) natural stiff fissured clays, and (b) overconsolidated peak, fully softened peak and residual strength envelopes (from VandenBerge et al. 2013).

The softening behavior, under drained long-term conditions, may occur in any clayey soil, but is most pronounced in highly plastic clays. The need to consider fully softened, drained strengths is greater in soils with higher plasticity index, the existence of fissures or shrinkage cracks, water contents above the shrinkage limit, higher clay fractions, lower silt or sand content, and higher activity (Duncan et al. 2011; VandenBerge et al. 2013). Long-term instability due to softening should be considered for (1) excavations in stiff fissured clays, where the stress relief caused by the excavation can lead to swelling, and (2) shallow sliding in compacted clay embankments, due to the formation of desiccation cracks from seasonal wetting-drying and freeze-thaw.

Fully softened strengths may be measured in triaxial or ring shear tests, but direct shear tests are preferred (Duncan et al. 2011; VandenBerge et al. 2013). Tests are conducted on remolded, normally consolidated samples that are initially mixed to water contents near the liquid limit, then consolidated back to void ratios matching the field conditions. Peak shear stresses from tests on the remolded samples are used to define the fully softened strength envelope, which should be the same as the drained, peak

strength of the soil when it is normally consolidated (Skempton 1970). When test data are unavailable, the fully softened strength can be approximated by using estimated, drained strength parameters (with c' = 0) for the soil in a normally consolidated condition.

In overconsolidated clays, the fully softened strength envelope is intermediate between the peak and residual drained strength envelopes (Figure 16). The fully softened strength envelope is curved, with essentially no cohesion (c' = 0 at σ' = 0). Hence, when using Mohr-Coulomb parameters for a linear fit, an envelope with c' > 0 will overestimate strengths at very low stress levels (shallow depths). Using an envelope with c' = 0 is conservative, but may be overly conservative when applied to soils at greater depths (higher stress ranges). An alternative is to model the nonlinear strength envelope, using secant friction angles, in the stability analysis (Stark et al. 2005).

In a slope, shear stresses along a potential failure surface are not uniform, and overstressed areas that lose shearing resistance past the peak strength will cause increasing shear stresses on other parts of the slip surface. This can lead to a progressive failure over time. The use of fully softened strengths in design, instead of relying upon the peak strength in strain softening soils, helps to avoid progressive failures (Skempton 1970).

When looking at the stress-strain test data, it is important to note if the laboratory tests were drained or undrained. Stiff, moderately to heavily overconsolidated clays usually exhibit significant strain softening behavior in drained shear. These soils are dilative, resulting in a loss of shearing resistance with localized expansion along the failure surface. Most laboratory tests on clayey soils are conducted using consolidated-undrained conditions. When dilative soils are subjected to undrained testing, a strain hardening behavior will be observed, because the dilative response will cause decreasing pore pressures and increasing effective stresses. Hence, strain hardening in undrained shear is an indicator of expected strain softening under long-term, drained shear.

Fully softened strengths are an important consideration when evaluating the stability of compacted embankments constructed of highly plastic soils. However, it is overly conservative to assume fully softened strengths throughout the full depth of an overconsolidated clay (Duncan et al. 2011; VandenBerge et al. 2013). One exception may be where an embankment is built over an earlier embankment, or foundation soil, that previously experienced softening.

The depth of softening is related to the depth of the excavation, the depth of seasonal moisture change, and/or the depth of desiccation cracking. The appropriate depth will depend on the characteristics of the soil, the climate at the site, and the geologic history. For embankments, the depth of softening may be limited to 2 to 3 meters at most sites, and up to 4 meters in some cases (Duncan et al. 2011; VandenBerge et al. 2013). Lesser depths of softening may be expected in regions without extreme wet and dry seasonal climates.

6.4. Depth of Surficial Softening

A compacted soil near the surface of an embankment may lose some of its drained shear strength (soften) over time. Softening in overconsolidated, fine-grained soils is associated with shrink and swell, due to seasonal variations in moisture content at shallow depths, and freeze-thaw. The development of fully softened strengths is discussed in Section 6.3.

For TVA dams, fully softened strengths are assumed to apply only in highly plastic CH or MH soils having a plasticity index greater than 40 (fine grained soils with LL > 50 and PI > 40). In these soils, the depth of softening is assumed to be 5 feet (measured normal to the ground surface). No softening is assumed on armored slopes that are covered with stone riprap.

6.5. Laboratory and Field Measurement

In the laboratory, values of c' and ϕ' can be measured in consolidated drained (CD) tests, or consolidated undrained (CU) tests with pore pressure measurements. CD tests are preferred, but CU tests are usually specified for low permeability soils where the time required for drained testing becomes excessively long. Effective stress failure envelopes measured with CU tests are typically close to those measured in CD tests, and the two test methods are usually assumed to give equivalent values of c' and ϕ'.

Triaxial compression tests are commonly specified for both CD and CU tests. Consolidated-drained tests can also be run in a direct shear apparatus, which is a valid option for measuring the drained strength of low permeability clays. Because relatively thin samples can be tested in direct shear, the time required for consolidation and loading to failure will be much less than in drained triaxial tests. Direct shear tests force failure along a horizontal plane, which may not be the weakest plane in an anisotropic soil, but can be used to measure the shearing resistance along carefully aligned bedding planes. Direct shear tests, especially those conducted using ring-shear devices, are particularly useful for measuring residual strengths at large shear displacements. These considerations can be usually neglected when coarse grained soils are tested in direct shear.

Effective stress parameters can also be estimated using empirical correlations with in situ penetration resistance. Correlations between ϕ' and Standard Penetration Test (SPT) blowcounts in sands are presented in Figure 17. Correlations with Cone Penetration Test (CPT) tip resistance are given in Figure 18.

6.6. Typical Values

Typical values of drained friction angles (ϕ') for sands and clays are given, respectively, in Figure 19 and Figure 20. Typical drained strengths in compacted soils are listed in Figure 3. These typical values are helpful in judging the veracity of results from laboratory tests or in situ penetration tests. Note that there is significant scatter in these correlations, particularly for the clay strengths in Figure 20.

Estimated strength parameters, estimated on the basis of these typical values, are sometimes used for non-critical soil materials in a stability analysis. However, where the strength parameters assigned to a soil layer are critical to the computed stability of the slope, those values should be backed up by testing.

6.7. Recommended Practice

Natural deposits of granular soils are often highly variable, as a result of their geologic history and means of deposition. Laboratory tests on a few discrete samples from such a deposit are valuable, but may not yield a complete understanding of the variability in shearing resistance in that deposit. Correlations to in situ, field penetration tests (SPT or CPT) may be preferred for characterizing the drained strength of a granular soil deposit, because one can consider many more data points and better understand variability across the deposit. The reasonableness of the results should be checked by comparison to typical values for similar soils, and may be verified with laboratory testing.

Significant variability may also be encountered in clayey soils, particularly in residual soils. However, whether formed in place by weathering or deposited in water, clay soils tend to be more uniform than granular soil deposits. Laboratory testing of field samples will give a useful measure of drained strength parameters for such soils. Consolidated undrained (CU) tests, with the measurement of pore water pressures, can be used to obtain drained, effective stress strength parameters.

In many (but not all) design problems involving fine grained or clay soils, the short term, undrained conditions will govern stability. In those cases, attention should focus on the accurate assessment of undrained strengths, and reasonable estimates of drained strength parameters based on published, typical values may be sufficient for checking long-term stability. In other design problems, long-term, drained conditions may govern, and careful attention must be given to the selection of appropriate effective stress strength parameters.

When determining drained strength parameters, the following practice is recommended:

(1) A cohesion intercept may be appropriate for cemented soils, as long as the cementation is permanent, and not apparent cohesion due to matric suction in an unsaturated soil.

(2) Values of $c' > 0$ may be used to represent segments of curved strength envelopes over specified pressure ranges.

(3) When fitting envelopes through scattered test data, a line forced through $c' = 0$ should be considered first (as opposed to mathematical regression fits). If a good fit to the data is obtained, then the values of $c' = 0$ and ϕ' from that fit should be used.

(4) Values of c' > 0 may be used, but only if supported by adequate test data. If there is little or no test data, and the drained strength parameters are estimated based on typical values, assume c' = 0.

(5) Cohesion may be neglected to avoid progressive failures and/or instability due to softening. Because a fissured soil mass often has a lower strength than laboratory test samples, design values of c' (for peak strengths) should not exceed about 200 psf in overconsolidated clays that may be fissured.

(6) Fully softened strengths may be appropriate for highly plastic, clayey or silty soils in compacted embankments, or in excavations in overconsolidated soils. Fully softened strengths are applicable only for shallow depths along an embankment surface, perhaps to a maximum depth of about 10 feet (measured perpendicular to the ground surface).

(7) Where test data indicates a strength envelope with c' > 0, the value of ϕ' fit to the data may be used with an assumed value of c' = 0. Setting c' = 0 in this manner for an overconsolidated clay provides a conservative approximation of the fully softened strength envelope.

(8) If a value of c' > 0 is critical to the stability of the slope, drained shear tests and/or tests on fully softened samples should be considered to support the selection of an appropriate drained cohesion intercept.

7. Undrained Strength Parameters for Static, Short Term Conditions

7.1. Basis

Soil shear strengths are characterized using undrained strength parameters where or when pore water pressures are unknown or cannot be predicted with confidence. Typically representing conditions where shear induced pore water pressures (excess or deficient) have not dissipated, the undrained shear strength (S_U) of a soil is expressed using undrained strength parameters (c and ϕ):

$$S_u = c + \sigma'_{con} \tan\phi \qquad \textbf{Equation 25}$$

In practice, the undrained shear strength of a soil may be expressed using UU strengths (Section 7.3.1), "c/p" ratios (Section 7.3.2), or R-envelopes (Section 7.3.3). In each case, undrained strengths are characterized as a function of effective consolidation stress (σ'_{con}), or sometimes approximated as a constant within a soil zone.

Undrained strength parameters are used in "total stress" stability analyses, where excess pore water pressures generated by shearing are unknown. The effective stresses prior to loading (σ'_{con}) are used to quantify the soil strength, but the analysis is carried out using total stresses (pore pressures and effective stresses in the soil under load are not estimated). The underlying assumption is that excess pore pressures generated in a laboratory test specimen are similar to those encountered in the field, so that the fundamental effective stress is similar in both cases. Undrained strength parameters fit to test data implicitly represent the effects of excess pore water pressure on the soil strength in the field.

Some engineers refer to S_U, c, and ϕ as "total stress strength parameters." This causes confusion, because effective consolidation stresses are used with the parameters to compute the shearing resistance (FERC 2006). The term "undrained strength parameters" is thus recommended for S_U, c, and ϕ.

It is challenging to measure and quantify undrained shear strengths that accurately represent the behavior of soils in the field. The assessment of undrained shear strengths is discussed extensively by Ladd (1991), Terzaghi et al. (1996), Ladd and DeGroot (2003), and Duncan et al. (2014). Undrained strengths are dependent on a number of factors, including:

- structural anisotropy in the soil (bedding planes, fissuring, etc.),
- stress history (preconsolidation stress or overconsolidation ratio),
- water content, void ratio, and degree of saturation in the soil,
- sampling disturbance in test specimens,
- mode of shearing (stress path or stress induced anisotropy),
- strain rate dependency, including creep effects, and
- potential for progressive failure in sensitive soils.

7.2. When to Use Undrained Strengths

Shearing resistance is fundamentally related to the effective stress in a soil, and drained strength parameters should be used with effective stress analyses any time the pore pressures (including shear-induced pore pressures) can be reliably predicted. However, when the soil is loaded rapidly, or any time when the shear induced pore water pressures are difficult to accurately predict, effective stress analyses are impractical and undrained analyses are necessary.

Under static conditions, pore pressures equilibrate fairly quickly in high permeability soils, such that undrained shear strengths are usually associated only with clayey or silty soil deposits. Coarse grained soils (sands, gravels, etc.) are often permeable enough that excess pore pressures will rapidly dissipate, even under short term loading conditions. For pervious soils, whether saturated or unsaturated, drained effective stress strength parameters may be used to represent short-term, undrained conditions. This assumes the static or steady-state pore water pressures in the soil are unchanged by the short-term loading, and the shear strength in an "undrained analysis" can be modeled using the drained, effective stress strength parameters.

Earthquakes are an exception, however. Dynamic loading will usually cause excess pore pressures to accumulate even in coarse grained soils. Undrained strengths for seismic conditions (Section 9) are needed for most soils.

To determine if a particular soil will be "drained" under a static load, the Time Factor (T) can be computed:

$$T = \frac{c_v t}{D^2} \qquad \textbf{Equation 26}$$

where c_v is the coefficient of consolidation, t is the elapsed time for the loading condition, and D is the drainage distance. If the Time Factor is greater than or equal to about three ($T \geq 3$), the soil can be assumed to drain; otherwise the soil should be treated as undrained (Duncan et al. 2014). Judgment is usually required to estimate a representative drainage distance when computing the time factor. In most rapid drawdown analyses, full drainage can be assumed in soils having a hydraulic conductivity greater than 10^{-4} cm/sec (USACE 2003; Duncan et al. 2014). These guidelines are reasonable for judging if a soil zone should be modeled as drained or undrained in most slope stability analyses, except for seismic or impact load cases.

The flowchart in Figure 21 provides guidance in the selection of drained versus undrained strength parameters for different soil conditions, based on the assumptions for the analysis. Clean, coarse sands are usually assumed to be fully drained under most loading conditions, but should be treated as undrained under dynamic, seismic, or impact loads. Clean rockfill, including riprap, can generally be assumed to drain even in an earthquake. Drained or undrained strength parameters may be appropriate to represent the strength of unsaturated soils, as discussed in Section 8.

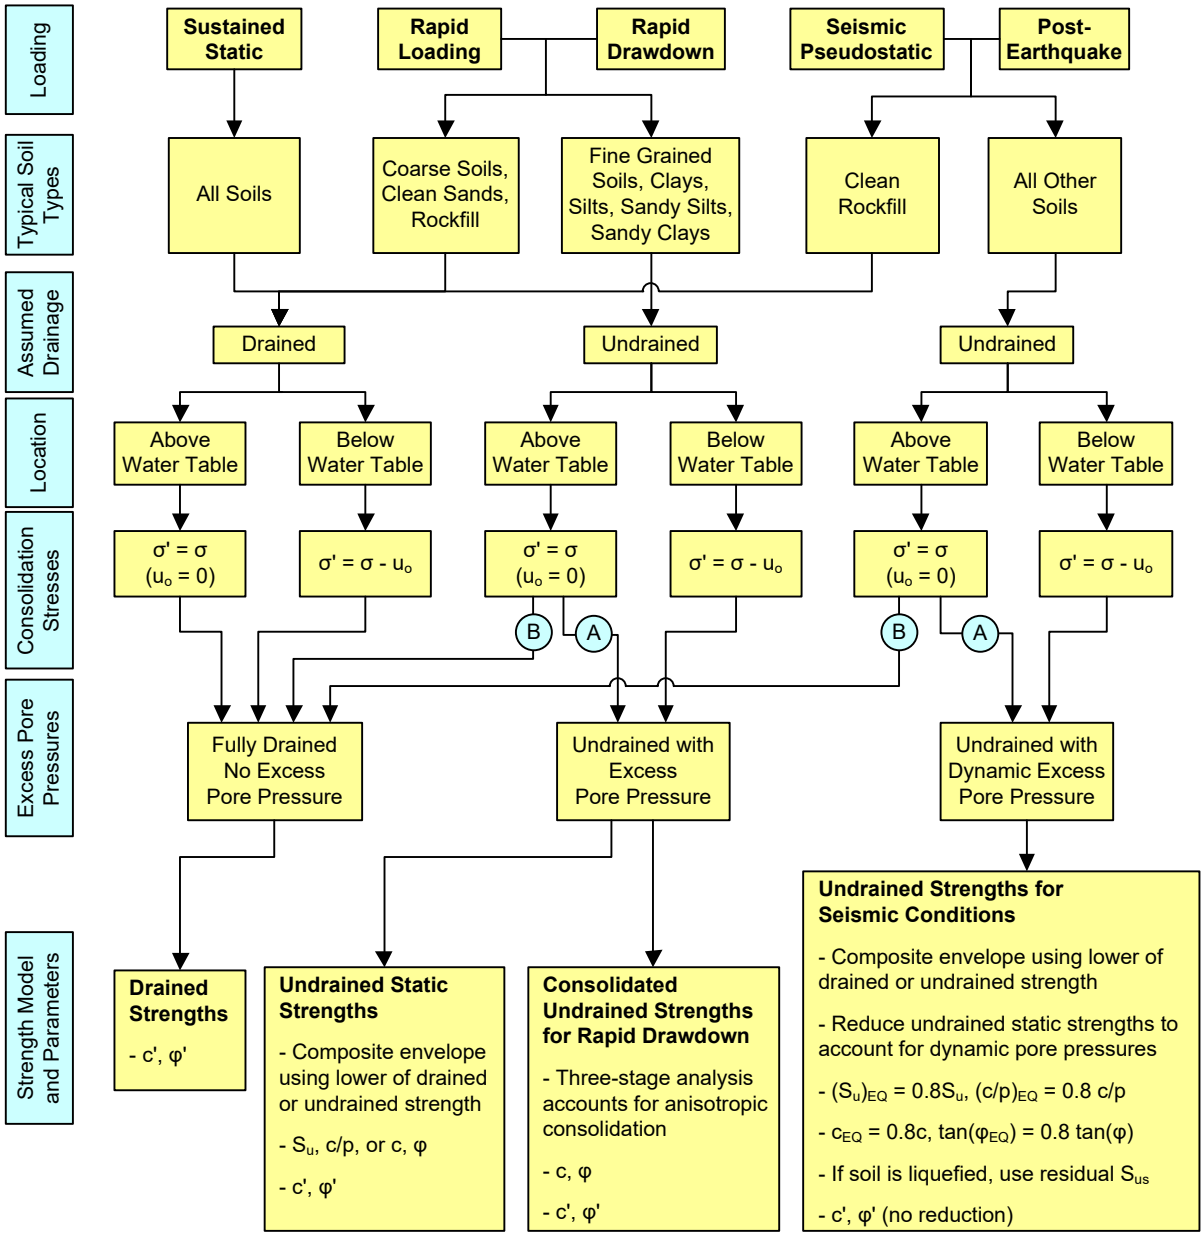

Figure 21. Selection of appropriate shear strength parameters for stability analyses.

7.3. Undrained Strength Parameters

7.3.1. UU Strengths

In unconsolidated undrained (UU) triaxial compression tests, soil samples are subjected to varying confining pressures and then loaded to failure. The samples are unconsolidated, in that no drainage from the soil is allowed as the confinement is increased. If the test samples are saturated, the applied confining pressure will cause a corresponding increase in pore pressure. Then, assuming all test samples are identical (same density), the effective stresses will be the same (in theory) regardless of the confining pressure. The undrained strength (S_U) is then independent of the confining stress ($\phi = 0$):

$$S_u = \text{constant} \qquad \textbf{Equation 27}$$

In practice, the void ratio of soil samples will decrease with depth and effective consolidation pressure, in samples taken from an otherwise uniform deposit. The undrained shear strength from UU tests will thus vary with the depth of the soil sample. In relatively thin or noncritical soil layers, a constant value of S_U may be used to model the entire deposit. In thicker deposits, values of S_U may be determined at various depths and the undrained strength profile might be modeled as a simple function of depth (z):

$$S_u = f(z) \qquad \textbf{Equation 28}$$

Unfortunately, the measurement of S_U in UU triaxial compression tests is fraught with problems, even when the tests are carefully executed in accordance with applicable standards. As detailed by Ladd (1991) and Ladd and DeGroot (2003):

- Unavoidable sample disturbance leads to S_U values that are too low.
- The high rate of shearing results in S_U values that are too high.
- Triaxial compression mode of shearing gives S_U values that are too high.

To get the "right" answer, these errors would have to offset one another. Engineering practice has generally assumed that the effects of sample disturbance dominate, leading to conservative measurements of S_U from UU tests. Ladd (1991) points out that this assumption may not be valid when better quality samples are obtained with modern tools and methods.

A value of S_U determined from a UU triaxial test is more appropriately viewed as an index of the soil's undrained strength, instead of a direct measurement. The relatively low cost of UU tests allows for conducting more laboratory runs, and can provide for a good compromise between testing costs and data quality. In addition, there is an extensive history of satisfactory performance when UU strengths are used in geotechnical design.

Historically, routine practice involved the use of unconfined compression tests to characterize the undrained shear strength (S_U = one half of the unconfined compressive strength) of clayey soils. However, unconfined compression testing

provides a poor, often low measure of soil strength. Specimens tend to dry during testing and, without confinement, dilatant soils are more apt to cavitate; both can cause desaturation of the soil. Unconfined tests should not be used with fissured clays, because of premature failure along the fissures (Terzaghi et al. 1996). UU triaxial tests, which involve little additional cost or effort, are nearly always preferred over unconfined compression tests.

7.3.2. c/p Ratios

To represent the variation in shear resistance with consolidation pressure, the undrained strength can be characterized using the "c/p ratio" ($c/p = S_u/ \sigma'_{1,con}$):

$$S_u = \left(\frac{c}{p}\right)\sigma'_{1,con} \qquad \textbf{Equation 29}$$

where $\sigma'_{1,con}$ is the major principal effective stress to which the soil has been consolidated. The c/p ratio concept is consistent with the experimental observation that the undrained strength of saturated clays varies with the water content (void ratio), which varies with the major principal effective stress to which the soil has been consolidated. The formulation in Equation 29, which avoids the theoretical limitations associated with R-envelopes (Section 7.4.3.3), is the preferred method for representing the undrained strength of soft, saturated soils.

The key to using this approach for a stability analysis is the determination of an appropriate, representative c/p ratio for the conditions of interest. Like S_U in general, values of the c/p ratio depend on the mode of shearing, stress history, sample disturbance, strain rate effects, etc. How these factors may be addressed in a laboratory testing program is outlined in Section 7.4.

For most normally consolidated soils, values of $c/p = 0.22 \pm 0.03$ are typical (Ladd and DeGroot 2003). The ratio will be larger for overconsolidated soils, and can be represented by the following empirical expression (Ladd 1991):

$$\left(\frac{c}{p}\right) = S \cdot OCR^{m} \qquad \textbf{Equation 30}$$

where S is an intercept value (where OCR = 1) and m is an empirical exponent (typical values of 0.75 to 1). Empirical values for estimating c/p ratios are presented in Section 7.6.

Here, the stress history of the soil deposit is represented by the OCR (overconsolidation ratio = preconsolidation pressure / effective stress). Application of Equation 30 in a stability analysis, and use of the c/p ratio in general, thus requires knowledge of the stress history. Accurate characterization of the preconsolidation stress (due to mechanical reductions in stress, desiccation, aging, or other physical-chemical process) is thus needed. Ladd and DeGroot (2003) provide specific recommendations for one dimensional consolidation testing to better quantify the preconsolidation stress.

The c/p approach works well for characterizing the undrained strength of soft clay deposits that are normally to moderately overconsolidated. In compacted embankments, where the preconsolidation stress is highly variable and difficult to quantify, the selection of a representative c/p ratio will be problematic. For unsaturated soils, the undrained strength measured in a UU test will vary with confining pressure, violating the assumption of $\phi = 0$. Therefore, c/p ratios are not recommended for modeling compacted embankment soils or unsaturated soils. Mohr-Coulomb strength parameters, or a single value of S_U (for layers or sublayers of moderate thickness), are usually better choices for such materials.

7.3.3. Undrained c and ϕ

The variation in undrained shear strength with consolidation pressure can also be represented using the Mohr-Coulomb envelope (Equation 19):

$$S_u = c + \sigma'_{con} \tan\phi \qquad \textbf{Equation 31}$$

where σ'_{con} is the effective consolidation pressure, and c and ϕ are undrained strength parameters (cohesion and friction angle, respectively).

This relationship gives the undrained strength on a potential slip surface as a function of the effective consolidation stress normal to the failure plane. When applied in a slope stability analysis, care must be taken to compute the undrained shearing resistance based on the normal stresses to which the soil has been consolidated (σ'_{con} in Equation 31). The steady state pore water pressures should be used in this calculation.

Traditionally, undrained strengths have been characterized using data from consolidated undrained (CU) laboratory tests that are fit with an "R-envelope" (traditional terminology employed by the U.S. Army Corps of Engineers). The undrained R-envelope (Figure 24) is a tangent line to "total stress" Mohr's circles, which are drawn for the consolidation pressure (σ'_{con}) and deviator stress at failure [$\sigma_{df} = (\sigma_1-\sigma_3)_f$]. When used to specifically represent R-envelopes, the undrained parameters are designated as c_R and ϕ_R.

The undrained shear strength obtained from a traditional R-envelope is less than the shear strength that would be measured in a CU test specimen at the same consolidation stress. This effect, and alternate definitions of the undrained strength envelope that may be employed, are discussed in Section 7.4.3.

7.4. Laboratory Measurements of Undrained Soil Strengths

7.4.1. Specimen Consolidation

Key details for handling soil samples and testing in the laboratory to measure undrained shear strengths in soft soils are provided in Ladd (1991) and Ladd and DeGroot (2003). High quality samples with minimal disturbance, generally obtained with thin-walled piston tube samplers, are essential for obtaining representative undrained strengths from laboratory tests. Even with careful handling of the field

sample and preparation of test specimens, the specimen will be affected by changes in stress during the extrusion process and the removal of the in situ stresses. Two methods may be employed during CU testing, to compensate for these effects:

- The Recompression technique (Bjerrum 1973) involves reconsolidating the test specimen back to the in situ stress conditions, prior to undrained shearing.

- The SHANSEP method (Ladd and Foott 1974) involves consolidating test specimens to stresses high enough to achieve virgin compression, then rebounding some so that the strength ratio can be characterized as a function of OCR (Equation 30).

The choice of methods depends on the nature of the soil being tested, as discussed by Ladd (1991), Ladd and DeGroot (2003), and Duncan et al. (2014). Where high quality block samples are available, the Recompression method is usually preferred. The SHANSEP method is preferred for normally to slightly overconsolidated clays, where Recompression to the in situ stress condition induces volumetric compression and a shearing resistance that is too high. The SHANSEP approach is often not practical for heavily overconsolidated soils, because of the high test pressures required; the Recompression technique should be used for such soils. Moreover, the Recompression technique should be chosen for highly structured, sensitive soils, where consolidation to virgin compression in the SHANSEP method will alter the soil structure and give undrained strengths that are too low.

Conventional laboratory triaxial tests consolidate test specimens under isotropic stress prior to undrained shear (designated as ICU or CIU tests). Testing anisotropically consolidated specimens (ACU tests) will generally produce higher and more accurate measurements of undrained shear strength. To simulate typical in situ stress conditions, Ladd (1991; Ladd and Foot 1974; Ladd and DeGroot 2003) advocates consolidating the test soils to K_o conditions ($\sigma'_h = K_o \sigma'_v$) in undrained tests designated as CK_oU.

Consolidated undrained test specimens are pressure-saturated prior to loading, to allow accurate measurement of pore water pressures. This eliminates suction pore pressures in unsaturated samples, but the absence of suction leads to conservative, lower shear strengths. Alternatively, the undrained shear strength of unsaturated soils can be characterized using UU triaxial tests.

7.4.2. Loading Path

The undrained strength also varies with the stress path imposed during shearing. The most commonly followed stress paths are triaxial compression (TC), triaxial extension (TE), and direct simple shear (DSS). Data presented in Terzaghi et al. (1996) and Ladd and DeGroot (2003) show that, for normally consolidated silts and clays:

$$\left(\frac{c}{p}\right)_{TC} > \left(\frac{c}{p}\right)_{DSS} > \left(\frac{c}{p}\right)_{TE} \qquad \textbf{Equation 32}$$

Duncan et al. (2014) point out that all three stress paths yield strengths that are lower than what would be measured under plane strain conditions. However, considering

the various modes of shearing in a slope stability problem, Ladd and Foott (1974) argue that DSS tests provide the best measure of the "average" shearing resistance along a potential slip surface.

Ladd (1991; Ladd and DeGroot 2003) favors the use of K_o-consolidated, direct simple shear (CK_oU-DSS) tests for providing the best measurement of undrained strength. Where DSS test data are not available, K_o-consolidated triaxial compression and triaxial extension tests (CK_oU-TC and CK_oU-TE) can be used. The average value of S_u from the TC and TE tests would then be used in the analyses. More importantly, Ladd argues that undrained strengths determined from CIU triaxial compression tests are too high and unsafe for design (see also Section 7.4.3).

7.4.3. Interpretation of Triaxial Test Data

When using data from laboratory triaxial tests, three different methods can be used to quantify the measured undrained shear strength. As described below, the undrained strength may represent the maximum shear stress $(S_u)_{ms}$, the shear stress from the R-envelope $(S_u)_R$, or the shear stress on the failure plane $(S_u)_{ff}$.

7.4.3.1. UU Tests - Maximum Shear Stress, $(S_u)_{ms}$

The shear strength measured in an unconsolidated undrained (UU) triaxial compression test represents the maximum shear stress in the soil at the time of failure. This shear strength, denoted $(S_u)_{ms}$, is the shear stress on a 45˚ plane in the triaxial test specimen. As depicted in Figure 22, $(S_u)_{ms}$ represents the top of the Mohr's circle of stress at failure, and is equal to one half of the applied deviator stress [$\sigma_{df} = (\sigma_1-\sigma_3)_f$]:

$$(S_u)_{ms} = \frac{\sigma_{df}}{2} \qquad \textbf{Equation 33}$$

The value of $(S_u)_{ms}$ is greater than the shear stress on the failure plane within the triaxial specimen. There are numerous other practical limitations associated with characterizing undrained strengths using UU test data, as outlined in Section 7.3.1. Strengths determined from UU triaxial compression tests represent an index of a soil's undrained shear strength. Hence, using $(S_u)_{ms}$ from a UU triaxial test is an acceptable means of characterizing the undrained shearing resistance on a potential failure surface in the field.

When using data from UU triaxial tests, the undrained shear strength in each test should be determined per Equation 33. Then, using the results from multiple tests, the undrained strength of the deposit may be characterized using:

- a constant value (Equation 27),
- a value that varies with depth (Equation 28), or
- a c/p ratio (Equation 29).

Depending on the quality and consistency of the samples, significant scatter or variation in the $(S_u)_{ms}$ values may be observed. A lower one-third value (where two-thirds of the values are higher), or perhaps the median value of $(S_u)_{ms}$, may be used to represent the soil. When using c/p ratios, a median or lower one-third value of the c/p ratio may be used.

7.4.3.2. CU Tests - Maximum Shear Stress, $(S_u)_{ms}$

To compensate for sample disturbance effects, undrained strengths can be measured using consolidated undrained (CU) triaxial tests. The undrained shear strength is sometimes taken as the maximum shear stress (Equation 33) in the test specimen at failure. The value of $(S_u)_{ms}$ is then plotted as a function of the effective consolidation stress (Figure 23). This interpretation is depicted on Figure 5.31 in Duncan et al. (2014).

However, values of $(S_u)_{ms}$ from CU triaxial compression results tend to be higher than the average shear strength that develops along a field failure surface, as discussed in Section 7.4.2. Therefore, the method shown in Figure 23 is <u>not</u> recommended for characterizing undrained strengths from CU test data.

7.4.3.3. CU Tests - Shear Stress from R-envelope, $(S_u)_R$

An R-envelope is developed by fitting a tangent line to Mohr's circles for the failure stresses measured in CU triaxial tests. The circles are drawn using the effective consolidation stress (σ'_{con}) as the minor principal stress and the deviator stress at failure (σ_{df}). The tangent R-envelope is then fit as shown in Figure 24, and characterized using Mohr-Coulomb parameters (c_R and ϕ_R).

$$(S_u)_R = c_R + \sigma'_{con} \tan \phi_R \qquad \textbf{Equation 34}$$

The strength parameters can also be determined by fitting a line to p-q points, as described in Section 5.2.

There are theoretical objections to the R-envelope formulation in Equation 34. The "Mohr's circles" are plotted using the effective stresses at the start of shearing and the stress difference at failure. Since these stresses do not exist at the same point in time, the plot is not actually a Mohr's circle (Duncan et al. 2014). Furthermore, Ladd (1991) argues that the R-envelope approach does not correctly represent the variation in undrained strength with the direction of the normal consolidation stress along a circular slip surface. The resulting errors are difficult to quantify.

On the other hand, R-envelopes have been widely used in past practice to represent the shear strength of soils under short-term conditions. This approach provides a conservative number for the undrained strength at a given consolidation pressure, as demonstrated in Section 7.4.3.5. For these reasons, a traditional R-envelope remains a valid approach for representing the variation in undrained shear strength with effective consolidation pressure. In particular, using the more conservative R-envelope may be preferred when characterizing the strength of a soil zone based on a limited number of CU test results.

R-envelope strength parameters (c_R, ϕ_R) are required for some analyses, such as for three-stage rapid drawdown calculations. That method explicitly accounts for the shear stress acting on the failure plane in a triaxial test sample.

7.4.3.4. CU Tests - Shear Stress on the Failure Plane, $(S_u)_{ff}$

In a triaxial compression test, failure should develop on a plane that is oriented at (45° + ϕ'/2) above horizontal (Duncan et al. 2014). The shear stresses on the failure plane can be determined using Mohr's circle. As depicted in Figure 25, a line drawn from σ'_{con} at (45° + ϕ'/2) above horizontal will intersect the Mohr's circle at the stresses on the failure plane. The shear stress on the failure plane at failure $(S_u)_{ff}$ can be computed using:

$$(S_u)_{ff} = \frac{\sigma_{df}}{2}\cos\phi' \qquad \textbf{Equation 35}$$

where σ_{df} is the measured deviator stress at failure. The shear stresses on the failure plane are employed explicitly in the three-stage calculation for rapid drawdown analyses.

The drained friction angle (ϕ') is required in Equation 35 to compute the shear stress on the failure plane in a CU test. Assuming pore pressures are measured, ϕ' can be obtained by fitting a drained strength envelope to data from the same CU test results. For a typical drained friction angle in the range of 30° to 35°, $(S_u)_{ff}$ will be 82% to 87% of the maximum shear stress $(S_u)_{ms}$.

Using data from several CU tests, the "undrained strength envelope" (FERC 2006; USBR 2011a) is fit to a plot of $(S_u)_{ff}$ versus specimen consolidation pressure (σ'_{con}). As illustrated in Figure 25, the undrained strength envelope is represented by Mohr-Coulomb parameters (c and ϕ).

Direct simple shear tests directly measure the consolidation pressure and shear stress on the (horizontal) failure plane. Hence, direct simple shear data can be fit directly to obtain c and ϕ.

Drained, undrained, and R strength envelopes are compared in Figure 26. Note that the values of c and ϕ for the undrained strength envelope are greater than c_R and ϕ_R for an R-envelope, which is tangent to the Mohr's circles of stress. Moreover, the undrained strength envelope should not be fit using p-q plots (Section 5.2).

7.4.3.5. Comparison of Shear Strengths from CU Tests

Three definitions for the undrained shear strength in a CU test are discussed above. For a certain consolidation pressure, these strengths will differ in magnitude as illustrated on Figure 27:

$$(S_u)_{ms} > (S_u)_{ff} > (S_u)_R \qquad \textbf{Equation 36}$$

Values of $(S_U)_{ms}$ from CU triaxial tests are unconservative and should not be used for design (Ladd 1991).

Values of $(S_U)_R$ may be obtained from R-envelopes fit to CU triaxial test results. This traditional approach tends to be conservative, in that the shear stresses within the triaxial sample are higher than the corresponding values of $(S_U)_R$ computed for the same consolidation pressure. This definition may be preferred when little test data is available to fit the strength envelope and a more conservative treatment is justified.

Values of $(S_U)_{ff}$ are rational and representative of the undrained strength measured in a CU triaxial test. The value $(S_U)_{ff}$ will always be higher than the corresponding value of $(S_U)_R$, and typically 80% to 90% of $(S_U)_{ms}$. This definition is justified when sufficient test data is available to perform a detailed or refined undrained analysis.

7.5. In Situ Measurements of Undrained Soil Strengths

Undrained shear strengths can also be assessed using in situ test methods, which avoid some of the problems related to sample disturbance in laboratory test specimens.

7.5.1. Standard Penetration Test Blowcounts

While values of S_U have been empirically related to Standard Penetration Test (SPT) data (Terzaghi et al. 1996), there is considerable uncertainty in such correlations. The rough correlation in Figure 28, from Peck et al. (1974), is qualitative in nature and should only be used to gauge the reasonableness of measured strengths. In very soft soils, SPT blowcounts (typically $N_{SPT} < 2$) are simply too insensitive for quantifying undrained strengths.

7.5.2. Cone Penetration Resistance

The tip resistance measured in a Cone Penetration Test (CPT) provides a better measurement of undrained shear strength in soft soils. The correlation is usually expressed as (Lunne et al. 1997):

$$S_u = \frac{q_t - \sigma_v}{N_{kt}} \qquad \textbf{Equation 37}$$

where q_t is the corrected CPT tip resistance, σ_v is the total overburden pressure, and N_{kt} is an empirical factor.

Unfortunately, the available empirical data show significant scatter, making the accurate quantification of S_U from CPT data difficult. Lunne et al. (1997) recommend

using N_{kt} = 15 to 20 as a preliminary estimate, while recognizing that values as low as N_{kt} = 10 may be appropriate for normally consolidated clays, and stiff fissured clays may exhibit N_{kt} = 30. To reduce this uncertainty, site-specific correlations between q_t and S_U (from field vane or laboratory testing) should be developed and used.

Ladd and DeGroot (2003) warn that poor quality CPT data, especially misleading pore pressure data, may undermine the reliability of such results. However, when used in conjunction with other site-specific measurements of undrained shear strength, CPT data can provide valuable knowledge on the variation of strength with location and elevation across the site.

7.5.3. Field Vane Shear Tests

The field vane (FV) shear test is generally considered the most reliable means of measuring undrained shear strength in situ. Recommended practice for FV testing includes the use of a thin vane blades with square ends, a gear system at the borehole surface (to rotate the vane at a controlled rate while accurately measuring the torque), and assessment of rod friction (Ladd and DeGroot 2003). To account for the effects of installation disturbance, fast rate of shearing, and the unique mode of failure, FV results should be adjusted using the Bjerrum's vane shear correction factor, μ (Figure 29). Values of μ were empirically determined using shear strengths back-calculated from slope failures.

Considering the scatter apparent in Figure 29, vane shear testing does not provide a precise measure of undrained shear strength. Despite this limitation, the vane shear test is the preferred test for measuring S_U in normally consolidated to moderately overconsolidated clays. The test results are less reliable where coarse inclusions (such as shells) are encountered (Ladd and DeGroot 2003). In silt deposits, which may be one to two orders of magnitude more permeable than clay, partial drainage is likely to occur in a vane shear test run at the standard rate of rotation. The measured shear resistance will then be higher than would be realized under fully undrained loading conditions.

7.6. Typical Values

Typical values and correlations are useful for making preliminary estimates of shear strengths, as well as for checking the reasonableness of field or laboratory test results. The table in Figure 28 indicates the range in S_U associated with the qualitative consistency of clays.

Mesri (1989) suggested this empirical relationship for S_U:

$$S_u = 0.22\,\sigma'_p \qquad \textbf{Equation 38}$$

where σ'_p is the preconsolidation pressure.

For soils with OCR = 1, the c/p ratio (Equation 29) has been empirically correlated to index properties as shown in Figure 30. Hansbo (1957) related the strength ratio in normally consolidated clays to liquid limit (LL):

$$\frac{c}{p} = 0.0045 \cdot LL \qquad \textbf{Equation 39}$$

Skempton (1957) related the strength ratio in normally consolidated clays to plasticity index (PI):

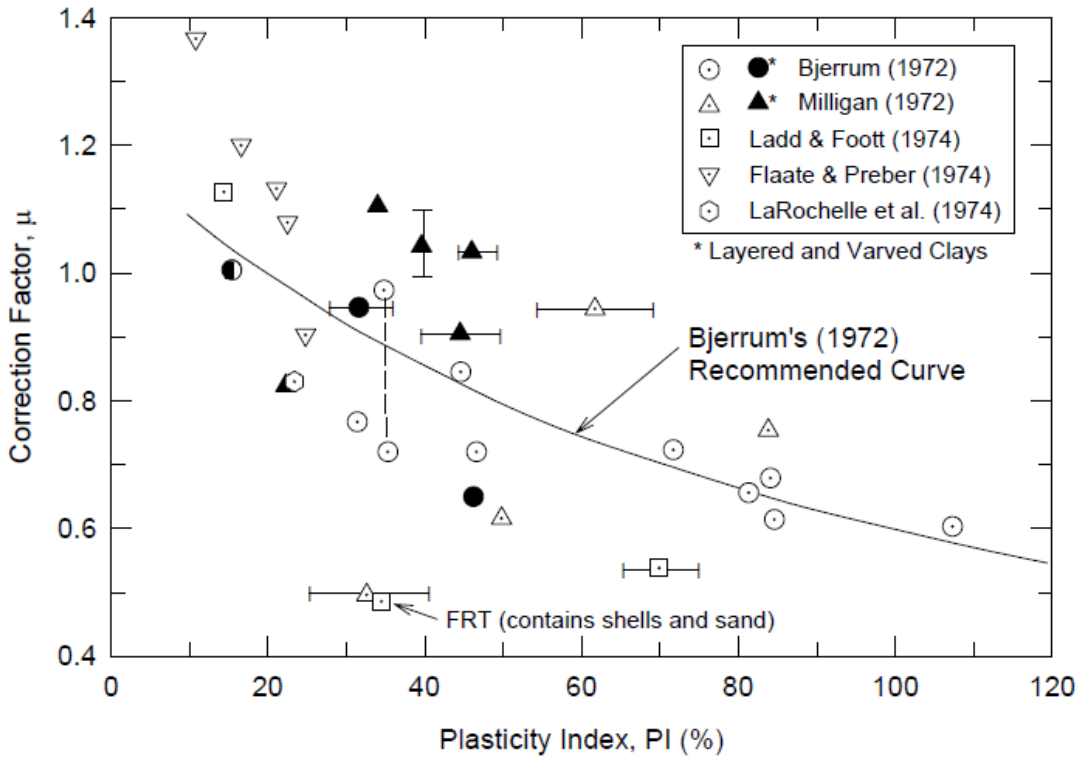
$$\frac{c}{p} = 0.11 + 0.0037 \cdot PI \qquad \textbf{Equation 40}$$

For normally consolidated to overconsolidated soils, typical values and correlations for S and m can be used with Equation 30 to estimate values of the c/p ratio. Suggested values of S and m for typical soils are listed in Figure 31.

Consistency	Field Identification	Undrained Shear Strength, S_u (psf)	Standard Penetration Test Blowcount* (blows/foot)
Very soft	Easily penetrated several inches by fist	< 250	< 2
Soft	Easily penetrated several inches by thumb	250 - 500	2 - 4
Medium	Can be penetrated several inches by thumb with moderate effort	500 - 1000	4 - 8
Stiff	Readily indented by thumb but penetrated only with great effort	1000 - 2000	8 - 15
Very stiff	Readily indented by thumbnail	2000 - 4000	15 - 30
Hard	Indented with difficulty by thumbnail	> 4000	> 30

** The correlation between undrained strength and SPT blowcount is rather unreliable*

Figure 28. Consistency of clays based on undrained strength (based on values from Peck et al. 1974).



$$S_u = \mu \left(S_u\right)_{vane}$$

Figure 29. Correction factor for the interpretation of undrained shear strengths from field vane shear tests (from Ladd and DeGroot 2003).

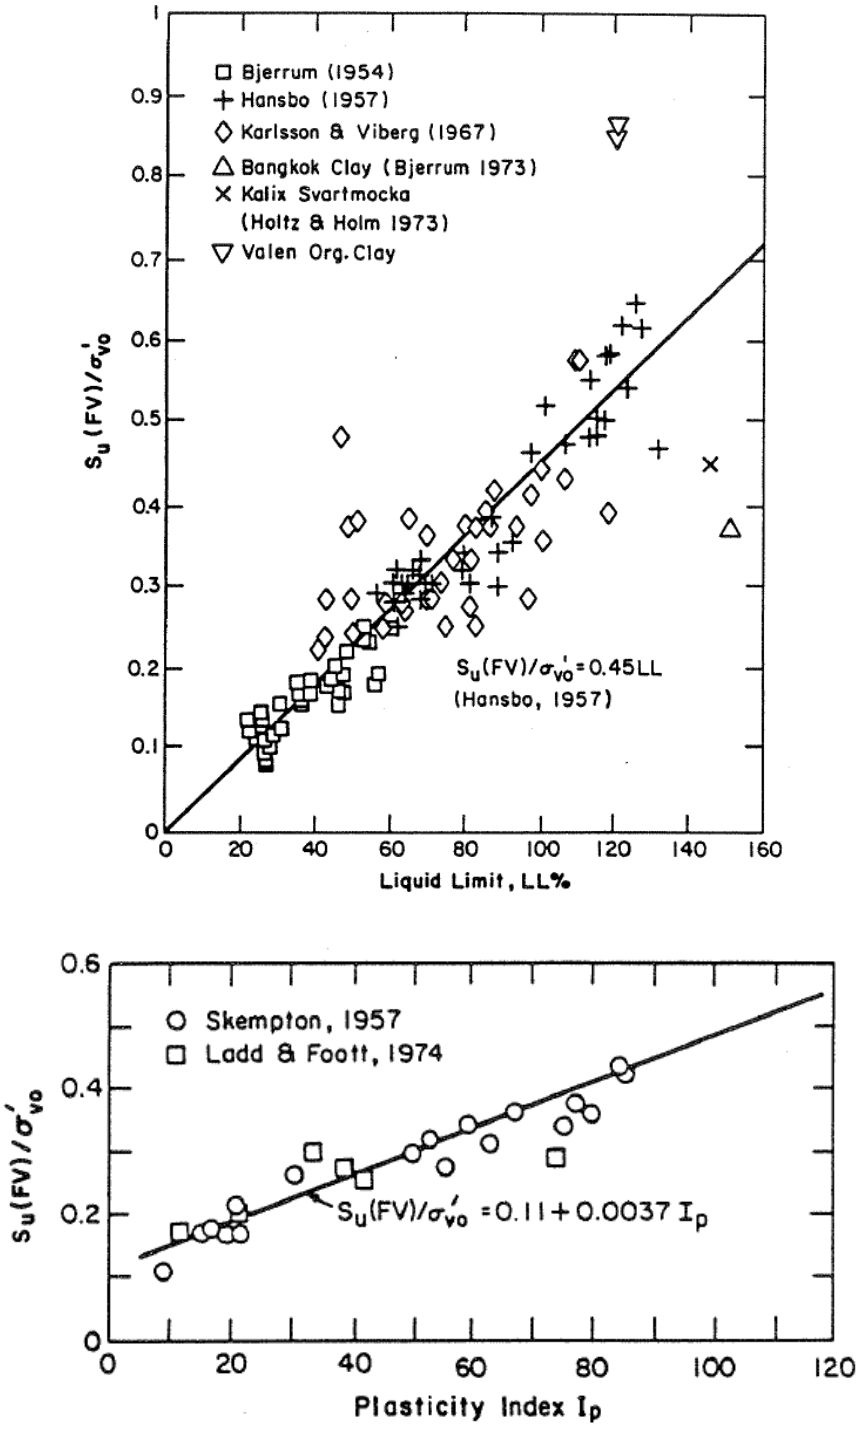


Figure 30. Correlations for c/p ratio in normally consolidated clays (from Duncan et al. 1989).

$$\left(\frac{c}{p}\right) = S \cdot OCR^{m}$$

Suggested, average values for most soils:

	S	m
Jamiolkowski et al. (1985)	0.23	0.8
Ladd (1991); Ladd and DeGroot (2003)	0.22 ± 0.03	0.8 ± 0.1

Suggested values for selected soils (Ladd and DeGroot 2003):

Soil Description	S	m[a]	Remarks
1. Sensitive cemented marine clays (PI < 30%, LI > 1.5)	0.20 Nominal SD = 0.015	1.00	Champlain clays of Canada
2. Homogeneous CL and CH sedimentary clays of low to moderate sensitivity (PI = 20 to 80%)	S = 0.20 + 0.05(PI/100) or Simply 0.22	$0.88(1 - C_s/C_c)$ ± 0.06 SD or simply 0.8	No shells or sand lenses-layers
3. Northeastern US varved clays	0.16	0.75	Assumes that DSS mode of failure predominates
4. Sedimentary deposits of silts and organic soils (Atterberg Limits plot below A-line) and clays with shells	0.25 Nominal SD = 0.05	$0.88(1 - C_s/C_c)$ ± 0.06 SD or simply 0.8	Excludes peat

[a] $m = 0.88(1 - C_s/C_c)$ based on analysis of CK_0UDSS data on 13 soils with max. OCR = 5 - 10

SD = standard deviation
C_s = swell index
C_c = compression index

Figure 31. Typical values for estimating the c/p ratio using Equation 30.

7.7. Recommended Practice

Accurately quantifying the shearing resistance of soils, when subjected to undrained loading, is a challenge. Where the stability of a slope depends on the behavior of soft or weak underlying soils, reasonable estimates of the undrained shear strength are

critical to the analysis and evaluation of the slope. This has been an active area for research throughout the history of modern geotechnical engineering, with disagreements and conflicting advice found in the literature. Moreover, there is usually a need to balance the need for accuracy and safety against the demands for engineering economy in the investigation, analysis, and design of earth structures. In these situations, the engineer must use appropriate judgment when specifying tests and selecting strength parameters for a stability analysis. It is neither feasible nor desirable to define a "recipe" procedure for selecting undrained soil strengths.

Based on the review outlined in this section, the following methods are recommended for the assessment of undrained soil strengths:

(1) Correlations and typical values for S_U and/or c/p ratios.

(2) Unconsolidated undrained (UU) triaxial compression tests:

- Perform numerous tests, measure S_U as one half of the deviator stress at failure, and expect significant scatter.
- Characterize S_U as a median value within a soil deposit, or as a function of depth.
- If there are sufficient data to characterize the consolidation pressure and stress history, characterize the variation in S_U using c/p ratios.

(3) Isotropically consolidated, undrained, triaxial compression tests (CIU TC):

- Fit a tangent line to Mohr's circles (or fit a line using p-q points), to define R-envelope parameters (c_R and ϕ_R). This is a traditional method that results in conservative values for the undrained shear strength, and is thus appropriate where few test results are available.
- Fit a line to the consolidation and shear stresses on the failure plane (Equation 35), to define parameters (c and ϕ) for the undrained strength envelope. This method is less conservative, and is recommended for refined analyses and where many test results are available.

(4) In situ field tests:

- Cone penetration tests (CPT) with site-specific correlations for S_U.
- Field vane (FV) shear tests, with empirical corrections (Figure 29) to obtain S_U.
- Characterize the results using a constant or representative S_U value, S_U expressed as a function of depth, or c/p ratios.

(5) Advanced laboratory testing:

- K_o-consolidated undrained triaxial compression (CK_oU TC) and triaxial extension (CK_oU TE) tests; use the average of S_U values measured in the two tests to define c/p ratios.

- K_o-consolidated direct simple shear (CK_oU DSS) tests, with results used to define c/p ratios.

Note that the use of c/p ratios requires knowledge of the stress history. In critical layers, one-dimensional consolidation tests are thus needed to define the variation in preconsolidation pressure with depth in the deposit. While c/p ratios work well for soft clay deposits, this approach is not recommended for characterizing unsaturated soils and/or compacted embankment soils.

In a roughly general sense, the costs and accuracy of the strength determination increases as one moves down the above list. Based on engineering judgment, more costly and better methods should be employed when characterizing more critical soil layers. Preliminary analyses accomplished with less expensive strength estimates may indicate the need for more in-depth considerations of stability, and the need for more sophisticated characterization of the undrained shear strength. More data from advanced testing can increase one's confidence in the strength parameters, which can also justify the use of smaller factors of safety and more economical designs.

7.8. Composite Drained-Undrained Strength Envelopes

Most soils will exhibit dilative shear behavior at low confining pressures. When saturated soils are consolidated to low effective stress and then sheared without drainage, the tendency to expand will cause decreasing pore pressures (suction). This results in increasing effective stress and shearing resistance, and an undrained strength that exceeds the drained strength. As indicated in Figure 32, the undrained strength envelope will be above the drained strength envelope in the regime of effective stress where the soil is dilative (generates suction pressures). Above a certain transition stress, the undrained strength will be less than the drained strength; in this higher stress range, the soil is contractive, creates increasing pressures in undrained shear, and the undrained strength is less than the drained strength.

The additional shearing resistance due to negative pore pressures may not be sustainable in the field. Over time, water will be drawn toward areas with suction pore pressures, the beneficial effects of the higher effective stress will be lost, and the soil strength will reduce to the drained shearing resistance. Hence, computed factors of safety for stability may be unconservative if some part of the slip surface has an undrained strength greater than the drained strength.

To avoid this issue, a composite (bi-linear) strength envelope (Figure 32) can be specified for undrained analyses. The undrained strength is then taken as the lesser of the undrained or drained strength envelopes at any given normal stress.

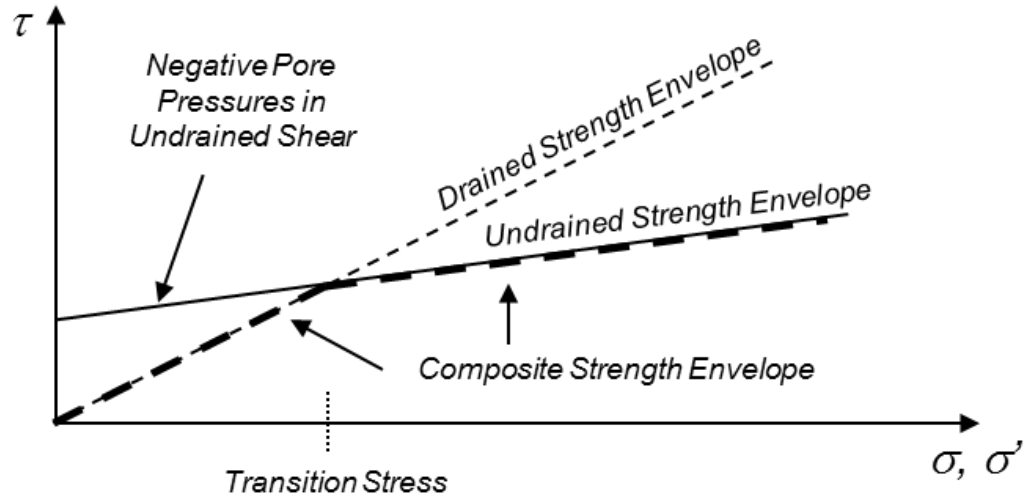

Figure 32. Specification of a composite strength envelope to avoid undrained shearing resistance due to negative pore pressures.

8. Strength of Unsaturated Soils

8.1. Saturation and Excess Pore Pressures

Shear-induced changes in pore pressure result from the movement of soil particles and the redistribution of stress between the soil skeleton and the pore fluid. Air is highly compressible, such that compression (or dilation) of pore space containing air does not generate significant changes in pore water pressure. In many unsaturated soils, shear induced volumetric changes will be accommodated by compression (or expansion) of the pore air. One might assume undrained loadings, including dynamic loadings, will not generate significant excess pore water pressures in these soils.

However, the actual behavior depends on the degree of saturation. Excess pore pressures are likely to occur in soils that are close to being saturated (perhaps at saturations greater than about 90 to 95%). For some soils above the water table, it will be appropriate and prudent to assume undrained loading will cause excess pore pressures and strength parameters should be assigned accordingly (Section 8.3).

Models of unsaturated soil behavior, including shear strength, can be formulated using the concept of "matric suction" (Fredlund and Rahardjo 1993). In most traditional geotechnical engineering problems, however, satisfactory results can be obtained without formal modeling of matric suction. Unsaturated soils may be modeled using conventional, drained or undrained strength parameters, as discussed below.

8.2. Conditions above the Water Table

The water table (phreatic surface) is defined as the line in the ground where pore water pressures are zero. Steady state pore pressures are positive beneath the water table and negative above.

Technically, the water table does not correspond to the top of the saturated zone. In the capillary fringe above the water table, the soils will be saturated or close to saturated. The height of capillary rise can range from a few inches in coarse sands to tens of feet in clayey soils.

In addition, soils above the water table may be saturated with retained water. For example, an embankment dam is subject to a changing phreatic surface as the reservoir rises and falls with dam operations. The phreatic surface drops when the pool is drawn down, inducing drainage from saturated zones above the new, lower water table. Significant water is retained in the pore spaces as the soil drains, with greater retention in finer grained soils. The infiltration and percolation of surface water will also increase the water content and degree of saturation in areas above the phreatic surface.

In assigning strength parameters for soils above the water table, it helps to consider how close to saturation the soil may be. Fine grained soils (silts, clays, sandy silts, sandy clays, etc.) are subject to greater heights of capillary rise, plus greater retention of draining or percolating ground water. Such soils may be close to saturation for

significant heights above the water table. Coarse sands with little fines experience less capillary rise and retain less water. The consideration of soil type is thus an important factor when selecting strength parameters for the unsaturated zone.

Regardless of saturation, the static pore pressures above the water table are negative (suction). Suction pressures increase the inter-particle stresses in the soil (represented by the effective stress) and the shearing resistance. However, in conventional stability calculations, pore pressures are assumed to be zero (absolute pressures equal to the atmospheric pressure) above the phreatic surface. Neglecting the suction pressures results in a conservative computation of consolidation stress and shearing resistance along the slip surface in the unsaturated zone.

8.3. Selection of Strength Parameters

The flowchart in Figure 21 helps to guide the selection of appropriate strength parameters for saturated and unsaturated soils. The chart is entered at the top, based on the loading condition that is being analyzed. Based on the loading rate and type of soil (see Section 7.2), each soil zone is judged to behave as fully drained or fully undrained. How the strengths are modeled may then depend on the whether the soil is found above or below the water table.

Under long-term, static loading conditions, the strength of all soils can be modeled using drained effective stress parameters. For clean, coarse soils, above or below the water table, drained strength parameters may be appropriate for all loads except dynamic, earthquake, or impact loads.

Rapid loading of fine grained soil induces undrained conditions in all cases, but the assigned strengths may differ if the soil is above or below the water table. Above the water table, the engineer has two options for the computing the strength under rapid or dynamic loads. The alternate paths are denoted A and B in Figure 21.

Along path A, excess pore pressures are assumed and undrained strengths are assigned (consolidation stresses are computed assuming zero static pore pressure). This path assumes the soil above the water table behaves as if it was saturated, and reduces the undrained strengths to account for dynamic pressures induced under seismic loading. This path leads to lower strengths and is thus conservative.

Path B in Figure 21 represents a less conservative approach that may be justified in some cases. For example, if the soil zone is well above the capillary fringe, the degree of saturation may be low enough to preclude the generation of excess pore pressures under load. This assumption may be valid for coarser soils that are closer to the water table. Along path B, drained strength parameters are assigned to zones above the water table.

For soils that are not located entirely above or below the phreatic surface, following path B will require specification of different soil zones above and below the water table (so that drained strengths can be assigned above, and undrained strengths can be applied below). The additional modeling effort may or may not be warranted or necessary, depending on the conditions under evaluation.

9. Undrained Strength Parameters for Seismic Conditions

9.1. Basis

Earthquakes generate cycles of shear stress that are rapid and transient. The stability of an earthen slope during an earthquake can be evaluated using pseudostatic analyses, simplified dynamic methods, or sophisticated numerical modeling. In each case, appropriate shear strength parameters must be estimated or measured for the undrained, seismic response of each soil.

To evaluate stability under these conditions, effective stress analyses (using c' and ϕ' strength parameters) are possible, but require a model for predicting the generation of excess pore water pressures under cyclic loading. A relatively high level of model sophistication is needed, along with good test data, to understand the volumetric response of the soil and track changes in effective stress during dynamic shearing.

A simpler approach is to use undrained stability analyses without predicting dynamic, excess pore pressures. Undrained shear strengths during an earthquake (S_{EQ}) can be characterized using undrained strength parameters, UU strengths, or c/p ratios:

$$S_{EQ} = c_{EQ} + \sigma'_{con} \tan\phi_{EQ} \qquad \textbf{Equation 41}$$

$$S_{EQ} = c_{EQ}, \text{ for } \phi_{EQ} = 0 \qquad \textbf{Equation 42}$$

$$S_{EQ} = \left(\frac{c}{p}\right)_{EQ} \sigma'_{1,con} \qquad \textbf{Equation 43}$$

Here, the "EQ" subscript designates parameters representing seismic (earthquake) loading conditions. Because cyclic shearing will generate additional pore pressures, above what might be expected under static shearing, undrained strengths for seismic loads (S_{EQ}) should be lower than for short-term static conditions (S_U). Much lower residual strengths (Section 10) are associated with soils that liquefy in an earthquake.

In most soils, the application of seismic shear stresses generates excess pore water pressures faster than they can dissipate. Undrained strength parameters are thus needed for most soils, even for granular soils that might be treated as fully drained under short-term, static loads. Exceptions might include clean gravels, rockfill, and stone riprap, all of which can usually be characterized using drained strength parameters in a seismic analysis.

9.2. Estimation of Dynamic Strengths

Cyclic shearing during an earthquake will generate additional pore water pressures in a soil. Higher pore pressures lead to softening and reduced shearing resistance, but soils that do not liquefy will retain most of their strength. Estimating appropriate strength parameters to represent these conditions is challenging. Given the inherent difficulties and incomplete knowledge of undrained soil behavior under dynamic loading,

geotechnical engineers have generally used judgment to arrive at appropriate strength parameters.

In their classic work on the seismic deformations of embankment dams, Makdisi and Seed (1977; 1978) recommended using a percentage of the static undrained shear strength to account for the potential loss of shearing resistance in unliquefiable soils during dynamic loading. They found that unliquefiable soils (clayey soils, unsaturated cohesionless soils, and very dense saturated cohesionless soils) exhibit essentially elastic behavior (no yielding) when subjected to many (> 100) cycles of stress at 80% or less of their static undrained shear strength. Substantial deformations generally result when these soils are loaded at higher cyclic shear stresses approaching their undrained shear strength. They thus concluded that for unliquefiable soils (i.e., soils that exhibit no more than small increases in pore pressure when loaded cyclically), the "cyclic yield strength" is, conservatively, at least 80% of the static undrained strength. Others have since used similar strength reductions to characterize the dynamic strength of unliquefied soils, in general.

Within the U.S. Army Corps of Engineers, Hynes-Griffin and Franklin (1984) recommend using reduced, undrained soil strengths in pseudostatic slope stability analyses. Specifically, they recommend using dynamic strengths equal to 80% of the undrained strength for both clays and unliquefied, pervious soils. While a reduced consolidated-undrained (R-type) strength envelope should be used for clayey soils, they recommend using a reduced, composite (bi-linear) drained-undrained (S-R type) envelope for pervious soils, to avoid relying on the increased shearing resistance due to decreasing pore pressures in dilative, granular soils (in this case, the drained strength parameters are not reduced).

Seed and Harder (1990) concluded that soils with a factor of safety against triggering of liquefaction (FS_{liq}) greater than 1.4 would experience only minor pore pressure generation under cyclic loading. Moreover, such soils could be represented in stability and deformation analyses using some large fraction of their static shear strength. For their analysis of the Lower San Fernando Dam failure, Seed and Harder (1990) assumed that granular soils with $FS_{liq} \geq 1.4$ retained 75% of their static strength (determined based on drained conditions) during the earthquake.

In summary, there is precedence for assuming that unliquefied soils will retain at least 80% of their static strength if they do not approach a liquefied state in an earthquake (U.S. Bureau of Reclamation 1999). This condition can be assumed to apply as long as $FS_{liq} \geq 1.4$ (the residual strength of liquefied soils is addressed in Section 10). A 20% reduction in strength can be represented using reduced short-term strength parameters:

$$c_{EQ} = 0.8\, c \qquad \textbf{Equation 44}$$

$$\tan(\phi_{EQ}) = 0.8 \tan(\phi) \qquad \textbf{Equation 45}$$

$$\left(\frac{c}{p}\right)_{EQ} = 0.8\left(\frac{c}{p}\right) \qquad \textbf{Equation 46}$$

When composite drained-undrained strength envelopes are used to avoid relying upon suction pressures for shearing resistance (Section 7.8), the drained strength parameters are not reduced.

9.3. Dynamic Strengths for Granular Soils

The residual strength of liquefied soils is discussed in Section 10.

As discussed in Section 7, undrained peak strengths are sensitive to a number of important details and can be difficult to accurately characterize. These difficulties are managed through the use of standardized test methods and prudent factors of safety, which have been established based on field experience. For fine-grained soils, there is a substantial base of experience, developed over the last century, to support the estimation, measurement, and appropriate application of undrained shear strengths to achieve acceptable field performance.

There is much less field or laboratory data, research, or design experience to support the selection of undrained strength parameters for unliquefied, clean, granular materials. Undrained loadings of such soils are uncommon, with the notable exception of seismic events. Laboratory determinations of in situ strengths are further inhibited by the great difficulty in obtaining undisturbed samples of these soils. Like clays, the determination of undrained yield strengths for sands from laboratory tests will be sensitive to details such as:

- relative density or void ratio of the test specimens,
- grain characteristics, including particle shape and gradation,
- effects of disturbance in "undisturbed" field samples,
- soil fabric resulting from the method of sample formation,
- consolidation stresses, including static shear stress,
- loading stress path (triaxial compression, extension, simple shear, etc.), and
- monotonic versus cyclic loading.

For sandy soils, the pre-earthquake shear strength under drained conditions (S_d, computed using effective stress) can be used to estimate the undrained shearing resistance (for undrained stability analyses) during and immediately after seismic loading. The 20% reduction in strength from the fully drained value is meant to account, in a simplistic manner, for the reduction in the undrained shearing resistance due to the generation of modest pore pressures during dynamic loading for unliquefied sands ($FS_{liq} \geq 1.4$). This approach has the advantage of indexing undrained strengths to ϕ', which can be estimated with relatively good confidence.

In addition, it is more difficult to reliably estimate peak undrained strength (S_U) than residual undrained strength (S_{us}) in a granular soil. Steady state concepts and back-analysis of liquefaction failures have been used to characterize residual strengths (Section 10.2), but ascertaining peak undrained strengths in field case histories is more difficult, and steady state concepts do not apply at the peak shear resistance. Hence, while considerable uncertainty remains in the estimation of residual strengths, peak undrained yield strengths can be estimated even less reliably. There is also a lack of field experience to judge what factors of safety should be considered adequate to ensure satisfactory performance, if that performance is predicted from such strength estimates.

9.4. Undrained Strengths for Pseudostatic Analyses

Pseudostatic stability calculations are carried out using limit equilibrium and the method of slices to compute a factor of safety for slope stability. The shearing resistance on the base of each slice can be computed using an undrained strength envelope (Equation 31), developed from consolidated undrained (CU) laboratory tests with a reduction for dynamic pore pressures (Section 9.2). The effective normal stresses on the base of each slice (σ'_{con} in Equation 31), representing the stresses to which the soil has been consolidated, should be computed using the steady state pore pressures prior to the earthquake.

In a simplified, single stage pseudostatic analysis, the value of σ'_{con} is computed from the total normal stress during the earthquake, which includes the inertial force (applied pseudostatic force). A more rigorous formulation involves a two-stage analysis (Duncan et al. 2014). The effective consolidation stresses normal to the failure surface (σ'_{fc}) are calculated in the first stage (without the pseudostatic force), and the undrained shear strength on that surface (τ_{ff}) is computed in the second stage calculations (with the pseudostatic force). A two-stage analysis requires a modified failure envelope:

$$\tau_{ff} = d_{EQ} + \sigma'_{fc} \tan\psi_{EQ} \qquad \textbf{Equation 47}$$

which can be derived from ϕ' and the seismic undrained strength parameters (c_{EQ} and ϕ_{EQ}):

$$d_{EQ} = c_{EQ}\left(\frac{\cos\phi_{EQ}\ \cos\phi'}{1-\sin\phi_{EQ}}\right) \qquad \textbf{Equation 48}$$

$$\psi_{EQ} = \arctan\left(\frac{\sin\phi_{EQ}\ \cos\phi'}{1-\sin\phi_{EQ}}\right) \qquad \textbf{Equation 49}$$

Duncan et al. (2014) considered a few typical cases, and concluded that a simplified, single-stage pseudostatic analysis should give a conservative estimate of the pseudostatic factor of safety in many cases.

10. Residual Strength Parameters for Liquefied Soils

10.1. Basis

A contractive, saturated sand sheared without drainage will exhibit a peak strength (S_u) followed by a residual shearing resistance with liquefaction at large strains. The residual strength (S_{us}), representing the shearing resistance of a liquefied soil in a steady state of deformation, may be very low. Some authors choose to identify the residual strength as S_r, to differentiate the residual, liquefied soil strength in the field from the steady-state strength in laboratory samples (Idriss and Boulanger 2008).

Soils are typically assumed to liquefy if the factor of safety against triggering of liquefaction (FS_{liq}) is less than or equal to 1.1. In their analysis of the Lower San Fernando Dam failure, for example, Seed and Harder (1990) assigned S_{us} values to soil zones that were indicated to have liquefied, based on $FS_{liq} \leq 1.1$.

The residual or steady state strength can be determined from laboratory tests on high quality "undisturbed" field specimens and reconstituted laboratory samples (Poulos et al. 1985). However, laboratory testing has been shown to give S_{us} values that are unconservatively high, compared to values back-calculated from field conditions (Castro et al. 1992; U. S. Bureau of Reclamation 1999). Correlations developed from liquefaction case histories and in situ penetration resistance (Section 10.2 and Section 10.3) are thus preferred for estimating S_{us} (USACE 2004).

10.2. Correlations based on SPT Blowcount

In the correlations presented in this subsection, the residual strength (S_{us}) or residual strength ratio (S_{us}/σ'_v) is related to SPT blowcount. Each of these correlations uses the corrected, normalized blowcount, $(N_1)_{60}$. The field blowcounts are normalized to one atmosphere of overburden pressure, corrected to 60% hammer efficiency, and adjusted for borehole diameter, short-rod energy loss, and sampler liner effects. The value of $(N_1)_{60}$ is the same as used to evaluate liquefaction triggering.

Some of the correlations presented below use SPT blowcounts that are also adjusted for the fines content of the soil. The corrected, clean-sand equivalent blowcount, $(N_1)_{60cs}$, is defined as:

$$(N_1)_{60cs} = (N_1)_{60} + \Delta(N_1)_{60cs} \qquad \textbf{Equation 50}$$

Approximate values of the fines content adjustment $\Delta(N_1)_{60cs}$ are:

% passing No. 200 sieve	$\Delta(N_1)_{60}$
10	1
25	2
50	4
75	5

Note that the above fines content correction, used in the residual strength correlations, is different than the fines content correction generally used in liquefaction triggering assessments.

Two published correlations for obtaining S_{us} from SPT blowcounts, both developed from limited case history data, are shown in Figure 33. Seed and Harder (1990) related S_{us} to the clean sand equivalent blowcount, while Stark and Mesri (1992) developed a correlation for the ratio of S_{us}/σ'_v. Seed et al. (2003) assert that Stark and Mesri's correlation is overly conservative at low pressure (σ'_v < 1 atm) and somewhat unconservative at high pressure (σ'_v > 3 atm). Seed et al. (2003) also acknowledge that the Seed and Harder (1990) correlation understates the influence of σ'_v on S_{us}.

According to Finn (1998), the practice at the U. S. Bureau of Reclamation has been to determine S_{us} at about the 35th percentile of Seed and Harder's (1990) correlation, using a line sketched between the upper and lower bounds. For $(N_1)_{60CS}$ greater than 15, Seed et al. (2003) recommend extrapolating the correlations in Figure 33 at constant slope. In addition, Seed et al. (2003) recommend that S_{us} should be limited to not exceed the fully drained shear strength (at the residual friction angle), which would require a reliance on significant negative pore pressures from the dilative response of soils at low pressures.

Olson and Stark (2002) used a larger case history dataset to develop correlations between the residual strength ratio and SPT blowcount (upper plot in Figure 34). The average trend line through the data is (Olson and Stark 2002):

$$\frac{S_{us}}{\sigma'_v} = 0.03 + 0.0075\,(N_1)_{60} \pm 0.03 \quad \text{for } (N_1)_{60} \le 12 \qquad \textbf{Equation 51}$$

where $(N_1)_{60}$ is the corrected, normalized SPT blowcount. The penetration resistance is not adjusted for fines content. A significant shortcoming of this correlation is the lack of field data for moderate to large confining pressures, corresponding to $(N_1)_{60}$ > 12.

Idriss and Boulanger (2008) examined the available case history data with the goal of providing better guidance on selecting strength ratios at higher penetration resistance. Among the challenges in developing these correlations, Idriss and Boulanger (2008) note the influence of "void redistribution" in a liquefied deposit, resulting from the migration of pore water within the soil during a liquefaction failure. Using the results from laboratory studies as a guide in extrapolating the case history data, Idriss and Boulanger proposed the two bounding relationships shown in the upper plot in Figure 35.

Where significant void redistribution might be expected, Idriss and Boulanger (2008) recommend a lower-bound estimate of residual strength ratio given by:

$$\frac{S_{us}}{\sigma'_v} = \exp\left[\frac{(N_1)_{60cs}}{16} + \left(\frac{(N_1)_{60cs} - 16}{21.2}\right)^3 - 3.0\right] \leq \tan\phi' \qquad \textbf{Equation 52}$$

Here, $(N_1)_{60CS}$ is the normalized, corrected SPT blowcount with the adjustment for fines content (Equation 50). The strength ratio is limited by the drained strength (tan ϕ'), based on the assumption that negative pore pressures (inferred by $S_{us} > \sigma'$ tanϕ') cannot be sustained. Significant void redistribution might be expected at "*. . . sites with relatively thick layers of liquefiable soil that are overlain by lower-permeability soils that would impede the post-earthquake dissipation of earthquake-induced excess pore water pressures*" (Idriss and Boulanger 2008). For example, Equation 52 would be appropriate for a thick layer of liquefied soil overlain by a clayey embankment.

Where void redistribution is judged to be unlikely, Idriss and Boulanger (2008) recommend an upper-bound estimate of residual strength ratio given by:

$$\frac{S_{us}}{\sigma'_v} = \exp\left[\frac{(N_1)_{60cs}}{16} + \left(\frac{(N_1)_{60cs} - 16}{21.2}\right)^3 - 3.0\right]\left[1 + \exp\left(\frac{(N_1)_{60cs}}{2.4} - 6.6\right)\right] \leq \tan\phi' \qquad \textbf{Equation 53}$$

This relationship is appropriately used for sites where void redistribution effects will be negligible. "*This condition could include sites where the stratigraphy would not impede post-earthquake dissipation of excess pore water pressures, [which] would be accompanied by densification of the soils at all depths*" (Idriss and Boulanger 2008). Where a rockfill dam is built over a relatively thin layer of liquefiable soil, for example, Equation 53 would be appropriate.

Various authors have preferred relationships between S_{us}/σ'_v and SPT blowcount. One can argue that penetration resistance should be correlated to S_{us}, instead of S_{us}/σ'_v. Steady state strengths measured in the laboratory have been shown to vary with void ratio (Poulos et al. 1985). After normalizing SPT blowcounts for the effects of overburden pressure, the value of $(N_1)_{60}$ should also correlate with the void ratio of a sandy soil. Hence, $(N_1)_{60}$ should correlate directly with S_{us}.

Three correlations for S_{us} in terms of $(N_1)_{60}$ or $(N_1)_{60cs}$ are shown in Figure 33a (Seed and Harder 1990), in the lower plot in Figure 35 (Idriss and Boulanger 2008), and in Figure 36 (Castro 1995). In Figure 36, the lower bound curve should be used to estimate liquefied strengths. Another correlation has been recently proposed by Kramer and Wang (2015):

$$\ln S_{us} = -8.444 + 0.109\,(N_1)_{60} + 5.379\,(\sigma'_v)^{0.1} \qquad \textbf{Equation 54}$$

where S_{us} and σ'_v are expressed in units of atmospheres.

10.3. Correlations based on CPT Tip Resistance

In addition to their correlation based on SPT blowcount, Olson and Stark (2002) used their database to develop a correlation between the residual strength ratio and CPT tip resistance (lower plot in Figure 34). The average trend line through the data is (Olson and Stark 2002):

$$\frac{S_{us}}{\sigma'_v} = 0.03 + 0.0143\,(q_{c1}) \pm 0.03 \quad \text{for } (q_{c1}) \le 6.5 \text{ MPa} \qquad \textbf{Equation 55}$$

Here, the normalized CPT tip resistance (MPa) is given by: $q_{c1} = 1.8 \cdot q_c / (0.8 + \sigma'_v/P_a)$. The penetration resistance is not adjusted for fines content. A significant shortcoming of this correlation is the lack of field data for moderate to large confining pressures, corresponding to $q_{c1} > 6.5$ MPa.

Idriss and Boulanger (2008) also used their database (Figure 35) to develop correlations based on CPT tip resistance. For sites without CPT data, they used empirical correlations to estimate the CPT resistance from the available SPT blowcounts. In these correlations, they use a CPT tip resistance (q_{c1N}) that is corrected for the effects of overburden pressure and normalized to a dimensionless value. The value of q_{c1N} is the same as used to evaluate liquefaction triggering.

Idriss and Boulanger (2008) also made an adjustment to account for the fines content of the soil. The normalized, clean-sand tip resistance, q_{c1Ncs}, is defined as:

$$q_{c1Ncs} = q_{c1N} + \Delta q_{c1N} \qquad \textbf{Equation 56}$$

Approximate values of the fines content adjustment Δq_{c1N} are:

% passing No. 200 sieve	Δq_{c1N}
10	10
25	25
50	45
75	55

Where significant void redistribution might be expected, Idriss and Boulanger (2008) recommend a lower-bound estimate of residual strength ratio given by:

$$\frac{S_{us}}{\sigma'_{vo}} = exp\left[\frac{q_{c1Ncs}}{24.5} - \left(\frac{q_{c1Ncs}}{61.7}\right)^2 + \left(\frac{q_{c1Ncs}}{106}\right)^3 - 4.42\right] \le tan\phi' \qquad \textbf{Equation 57}$$

Where void redistribution is judged to be unlikely, Idriss and Boulanger (2008) recommend an upper-bound estimate of residual strength ratio given by:

$$\frac{S_{us}}{\sigma'_{vo}} = exp\left[\frac{q_{c1Ncs}}{24.5} - \left(\frac{q_{c1Ncs}}{61.7}\right)^2 + \left(\frac{q_{c1Ncs}}{106}\right)^3 - 4.42\right]\left[1 + exp\left(\frac{q_{c1Ncs}}{11.1} - 9.82\right)\right] \le tan\phi' \qquad \textbf{Equation 58}$$

10.4. Recommended Practice

Considering the number of published correlations, and the uncertainty associated with each one, the recommended practice is to estimate S_{us} from all applicable correlations. The average or representative blowcount (or CPT tip resistance) in the soil layer should be used in the correlations to estimate S_{us}. Then, engineering judgment should be used to select an appropriate, representative value. Caution is needed to avoid over- or under-estimating S_{us} at confining pressures that are significantly higher or lower than the data set used to derive the correlations.

11. Residual Strength Parameters for Cyclic Softened Soils

For $FS_{\gamma=3\%}$ estimates less than one, the undrained strength may degrade during earthquake shaking. This behavior may be significant in deformation analyses. The post-earthquake strength of cyclic softened soils may range from the peak undrained strength (S_u) for small cyclic shear strains to the undrained, remolded strength (S_{ur}) at large cyclic shear strains. For clay-like soils with $FS_{\gamma=3\%}$ estimates less than one, using S_{ur} for softened soil horizons in an initial post-earthquake stability or deformation analysis can identify if the softened layers are a concern for post-earthquake stability. If this simple evaluation indicates a potential stability problem, additional evaluation is required to determine if S_{ur} or a greater strength is appropriate.

Laboratory strength tests for S_u and S_{ur} are typically required for high-consequence projects. Post-cyclic monotonic triaxial compression and direct simple shear tests are also valuable in identifying the degradation in peak undrained strength for modest strains. A more extensive discussion of laboratory test methods is provided in MSHA (2010).

11.1. Field and Laboratory Measurements of Remolded Strength

Measurement of S_{ur} requires a device that can achieve large strains, such as a field vane shear apparatus. Field tests are often performed adjacent to CPTs with pore pressure measurements to permit selection of suitable soil layers for testing. Field vane tests should follow accepted procedures, must be performed to high enough strains to mobilize S_{ur}, and must be conducted rapidly enough to capture the undrained behavior of the soil. Laboratory tests on saturated, remolded samples tested at the in situ water content may also be used.

Data from CPT can also be used to estimate remolded strength of clays. According to Lunne et. al (1997), the undrained, remolded shear strength (S_{ur}) of a clay is approximately equal to the sleeve friction measured with a CPT.

12. Properties of Rockfill

12.1. Basis

Coarse rockfill is difficult to characterize by testing. When a material contains cobbles or boulders, it is difficult to obtain representative samples and conduct meaningful tests with conventional laboratory equipment. Large-scale tests reported in the literature provide valuable data on the engineering properties of rockfill (Figure 39), but relatively few such tests have been published. However, appropriate properties can be usually selected on the basis of engineering judgment, where that judgment is supported by the performance of similar materials in other projects.

In the laboratory, the diameter of triaxial test specimens should be at least six times the size of the largest particle (Duncan et al. 2014). Most geotechnical laboratories have equipment for testing 4-inch diameter specimens, and a few facilities can test up to 12-inch samples. The largest particle size that can be tested in this equipment is then 0.7 to 2 inches. For gravelly soils, test samples re-mixed to have parallel grain-size distributions, or scalped to remove particles larger than one-sixth the specimen diameter, will generally have friction angles similar to the original material; however the relative density and gradation of the original material must be known with some confidence.

Testing samples without the largest particles is not recommended for rockfill with cobbles and boulders. There is a tendency for smaller particles to be stronger than larger particles (which may have internal fractures or discontinuities), and removing the larger particles may result in unconservative measurements of strength. Direct measurements on rockfill require testing large volumes of representative material. Few large triaxial compression apparatuses have been developed, and those were generally used for a specific project and are no longer in operation.

Fortunately, rockfill materials exhibit favorable engineering behavior. If the rockfill is relatively clean (voids between the larger rock particles are open), potential excess pore pressures will quickly dissipate. Depending on the gradation, fully drained conditions can often be assumed in rockfill under a variety of loading conditions, including under dynamic or seismic loads. Interlocking between large, angular pieces of durable rock will result in relatively high shear strength. Satisfactory performance in these materials can usually be demonstrated, even when conservative estimates of strength are used.

Published results from large-scale testing show how certain conditions affect the strength of rockfill. In general, friction angles decrease with increasing confining pressure, increasing particle size, and weathering over time. Well graded material generally has higher friction angles than poorly graded material. Angular to sub-angular material generally has higher friction angles than rounded to sub-rounded material. Mineralogy has little effect on friction angle.

Over a large pressure range, rockfill materials exhibit curved strength envelopes. This can be represented using secant friction angles that vary with confining pressure, as

discussed below. The secant friction angle (ϕ'_{sec}) is the slope of a tangent line to the Mohr's circle of stress at failure, with zero cohesion intercept, as depicted in Figure 37.

12.2. Historical Data

During construction of South Holston Dam, TVA performed large-scale tests to determine the friction angle of the quarried and dumped rockfill. Those tests, discussed by Leonard and Raine (1958), consisted of filling a 9.3-feet by 9.3-feet shear box with 6 to 12-inch diameter, quarried rock. The rockfill was vibrated during placement, and was about 3 feet thick when tested. Concrete slabs (total thickness of 6 feet) were placed on top of the apparatus for added confining load. Hydraulic jacks were used to apply a horizontal force until lateral displacement occurred. Three materials were tested: cemented sandstone, uncemented sandstone, and shale.

Data from the specific tests were not published, but Leonard and Raine (1958) reported measured friction angles of 45 degrees for the cemented sandstone, and about 30 degrees for the uncemented sandstone and shale. For design, a friction angle of 45 degrees was used for the downstream slope, where durable sandstone was placed. On the upstream face, a mix of the quarried rock was placed and a friction angle of 40 degrees was assumed. Although the method of measurement is unknown, Leonard and Raine (1958) report that dry unit weights for the rockfill were between 105 and 120 pounds per cubic foot.

The large-scale tests at South Holston Dam were conducted at rather low confining pressures (less than 900 psf). Granular materials, including rockfill, are known to exhibit curved failure envelopes, with secant friction angles that decrease at higher confining pressures. Hence, the South Holston friction angles reported by Leonard and Raine (1958) may be unconservatively high for representing the material strength under significantly higher confining pressures.

12.3. Published Research

Marachi et al. (1972) performed tests on 36-, 12-, and 2.8-inch diameter specimens of rockfill in drained triaxial compression equipment. Three types of rockfill were tested; argillite from Pyramid Dam, quarry blasted crushed basalt, and amphibolite from Oroville Dam. The test specimens were prepared to have grading curves parallel to the field gradation curves. The confining pressures for the tests ranged from 30 to 650 psi. The results of these tests (Figure 38) show a nonlinear Mohr-Coulomb strength envelope, with decreasing secant friction angles over the range of confining pressures tested. The results also show that for larger maximum particle size, the secant friction angle is less at a given confining pressure.

Leps (1970) compiled the database of rockfill test results in Figure 39, and showed the effects of normal pressure on drained friction angle. The data are plotted in Figure 40 on a semi-log graph of secant friction angle versus normal pressure. The data shows that at lower normal pressure, the decrease in friction angle is greater with increasing normal pressure than at higher pressures. The three trend lines in Figure 40 were defined by Leps (1970) for the range of typical rockfill; the trend lines can be represented by the following equations:

- Low density, poorly graded rockfill, with weak particles (unconfined compressive strength between 500 and 2,500 psi)

$$\phi'_{sec} = 41.8° - 6.8° \log\left(\frac{\sigma'_n}{P_a}\right) \quad \textbf{Equation 59}$$

- Average rockfill, with average strength particles (unconfined compressive strength between 2,500 and 10,000 psi)

$$\phi'_{sec} = 47.1° - 6.8° \log\left(\frac{\sigma'_n}{P_a}\right) \quad \textbf{Equation 60}$$

- High density, well graded rockfill with strong particles (unconfined compressive strength between 10,000 and 30,000 psi)

$$\phi'_{sec} = 52.1° - 6.8° \log\left(\frac{\sigma'_n}{P_a}\right) \quad \textbf{Equation 61}$$

Here, ϕ'_{sec} is the secant, effective stress friction angle (slope of a tangent line to the Mohr's circle of stress at failure, with zero cohesion intercept), σ'_n is the effective normal pressure on the failure plane, and P_a is one atmosphere of pressure in the units of σ'_n (P_a = 14.69 psi = 2,116 psf = 101.3 kPa).

Fell et al. (2005) present an empirical correlation, developed by Douglas (2003), for the secant friction angle of rockfill. This equation can be used to estimate the friction angle of the material using gradation data, normal stress, and unconfined compressive strength of the rock.

$$\phi'_{sec} = a + b\,{\sigma'_n}^{c} \quad \textbf{Equation 62}$$

$$a = 36.43 - 0.267ANG - 0.172FINES + 0.756(c_c - 2) + 0.0459(UCS - 150) \quad \textbf{Equation 63}$$

$$b = 69.51 + 10.27ANG + 0.549FINES - 5.105(c_c - 2) - 0.408(UCS - 150) - 0.408 \quad \textbf{Equation 64}$$

$$c = -0.3974 \quad \textbf{Equation 65}$$

ANG is a subjective rating for angularity; use ANG = 3 for crushed angular rock, ANG = 0 for rounded stone. FINES is the percentage of particles passing the No. 200 sieve (< 0.075 mm). From the gradation curve, c_c is the coefficient of curvature ($d_{30}^2/d_{10}d_{60}$). UCS is the unconfined compressive strength of the rock, in MPa, and σ'_n is the effective normal stress in kPa.

With this method, a multi-linear strength envelope can be used to represent the curved Mohr-Coulomb envelope typical of rockfill. This can be plotted by calculating ϕ'_{sec} at varying σ'_n applicable to the stability analysis. Loose dumped rockfill at low normal

pressures will have a secant friction angle approximately 4 degrees lower than calculated using this approach (Fell et al. 2005).

The method proposed by Douglas (2003) may be difficult to implement, because rockfill can be difficult to sample and the gradation may be unknown. If the rock is not durable, weathering may lead to significant changes in gradation over time after construction. The unconfined compressive strength may have to be estimated, if intact samples are not obtained. Finally, the subjective definition of "angularity" introduces additional uncertainty.

12.4. Curved Strength Envelopes in Slope/W

A single, representative friction angle can be selected to model the strength of a relatively thin or shallow rockfill layer. In deep rockfills, such as in the shell of a large rockfill dam, the confining pressure varies over a wide range and the strength model should represent a curved envelope, consistent with the test data discussed in Section 12.3. Some computer codes include an option for directly modeling variable secant friction angles, using equations like those in Equation 59 through Equation 61. The SLOPE/W code (from GEO-SLOPE International, Ltd) does not include this option, but will allow the user to specify points on a curved strength envelope. This can be accomplished using the procedure outlined below.

A curved strength envelope and a secant friction angle (for the Mohr's failure circle at one confining stress) are depicted schematically in Figure 37. Technically, the line at ϕ'_{sec} is not tangent to the Mohr's circle of stress at the same point as for the curved strength envelope, but the difference is not significant. Points on the curved strength envelope can be computed as follows:

(1) Select a range of normal stresses (σ'_n) that span and bracket the problem of interest.

(2) At each σ'_n, determine an appropriate ϕ'_{sec} for the material (for example, using the empirical equations in Section 12.3).

(3) At each σ'_n, compute the shear stress on the failure surface (τ_f) using:

$$\tau_f = \sigma'_n \tan \phi'_{sec} \qquad \textbf{Equation 66}$$

(4) Include a point at the origin ($\sigma'_n = 0$, $\tau_f = 0$), even if ϕ'_{sec} is not defined at zero stress.

These values of (σ'_n, τ_f) are then entered into SLOPE/W, which will interpolate between the entered values (using a spline function) to obtain the shear resistance at any normal effective stress.

SLOPE/W requires linear strength envelopes for three-stage rapid drawdown analyses. In this case, the needed strength parameters can be obtained from an approximate, straight line fit to values of (σ'_n, τ_f) in the appropriate stress range.

1.0 INTRODUCTION

Stantec Consulting Services Inc. (Stantec) has prepared this sampling and analysis report (SAR), on behalf of the Tennessee Valley Authority (TVA), to document activities related to the seismic stability analyses at TVA's Kingston Fossil Plant (KIF Plant) located in Harriman, Tennessee (see Exhibit A.1 in Appendix A).

The purpose of the Seismic Stability SAR is to develop slope stability models, including material parameters, and perform slope stability analyses for the selected coal combustion residuals (CCR) units, in support of fulfilling the requirements for the Tennessee Department of Environment and Conservation (TDEC) issued Commissioner's Order No. OGC15-0177 (TDEC Order) to the TVA (TDEC 2015). The TDEC Order set forth a "process for the investigation, assessment, and remediation of unacceptable risks" at TVA's coal ash disposal sites in Tennessee.

The purpose of this Seismic Stability SAR is to summarize activities completed to meet the objectives of the Stability Sampling and Analysis Plan (SAP) (Stantec 2018a), for applicable seismic load cases. Static load cases (if any) required by the SAP are documented in a separate Static Stability SAR. This SAR presents results of seismic stability analyses (also referred to herein as stability analyses) and compares those results to acceptance criteria defined in the SAP. However, this SAR is not intended to provide conclusions of the stability analysis. The scope of the stability analysis activities represented herein was conducted pursuant to the SAP and is part of a larger environmental investigation at the KIF Plant. The evaluation of the results will consider other aspects of the environmental investigation, as well as data collected under other State and/or CCR programs and will be presented in the Environmental Assessment Report (EAR).

The Seismic Stability SAR activities were performed in general accordance with the following documents developed by TVA to support fulfilling the requirements of the TDEC Order:

- Stability SAP (Stantec 2018a)
- Environmental Investigation Plan (EIP) (Stantec 2018b)
- Quality Assurance Project Plan (QAPP) (Environmental Standards, Inc. 2018).

2.0 OBJECTIVE AND SCOPE

The primary objective of the Seismic Stability SAR, conducted pursuant to the Stability SAP, was to develop slope stability models, including material parameters, and perform seismic stability analyses for select CCR units at the KIF Plant, in response to the TDEC Order. The Stability SAP included slope stability models and seismic, global analyses at two cross sections at the Sluice Trench and Ballfield East of the Sluice Trench: Section A-A' and the "Polishing Pond" Section. Cross sections are presented in Section 4.2. The Stability SAP also included seismic, veneer stability analyses at a typical cross section at the Sluice Trench and Ballfield East of the Sluice Trench. The approach for the Seismic Stability SAR was to:

- Review historical and TDEC Order subsurface explorations of the site to characterize the subsurface conditions
- Review and compile historical and TDEC Order laboratory testing of materials to determine material properties
- Evaluate the liquefaction potential for the defined materials
- Conduct the required global and veneer stability analyses for the various load cases, including a deformation analysis as part of the pseudostatic load case.

The scope of work of the Seismic Stability SAR consisted of the following tasks:

- Develop material properties and strengths
- Model the subsurface conditions at each cross section, including the phreatic surface
- Conduct global stability analyses for the required load cases (pseudostatic and/or post-earthquake)
- Conduct veneer stability analyses for the required load cases (pseudostatic)
- Compare results against the acceptance criteria defined in the SAP; for cases (if any) not meeting the acceptance criteria, further assessment will be appropriate per the phased approach defined in the Stability SAP.

Table 1 provides the stability analyses (i.e., load cases) conducted for each CCR unit. In cases where new analyses were not performed, existing analyses adequately address the load case(s) for the unit.

Table 1. Stability Analyses Completed for each CCR Unit

CCR[1] Unit and Condition	Seismic Cases		
	Pseudostatic[2], Global	Pseudostatic[2], Veneer[3]	Post-EQ[4], Global
Interim Ash Staging Area (Closed Condition)	–[5]	–[5]	–[5]
Sluice Trench and Ballfield East of Sluice Trench (Closed Condition)	X	X	X
Stilling Pond (Closed Condition)	–[6]	–[6]	–[6]

Notes:
1. CCR = coal combustion residuals
2. Pseudostatic, correlated to a tolerable displacement
3. Veneer stability is the slope stability of the final cover
4. Post-earthquake (Post-EQ) analysis includes a preceding liquefaction triggering assessment
5. Stability calculations are not required to demonstrate performance of the closed conditions due to the higher surrounding grade, flat closure grading, and containment towards the east by the Polishing Pond
6. The reassessment of the Stilling Pond closure design includes analyses sufficient to address the necessary load cases.

The SAP includes a phased assessment process for the stability analyses. Initial phases employ available site information, simplified analysis methods, and more conservative acceptance criteria. If acceptable performance is demonstrated, the analyses for the particular load case(s) are complete. If not, the next phase may include collection of additional site information and/or more advanced analysis methods. Less conservative acceptance criteria may be utilized, commensurate with the improved site characterization. For the KIF Plant, Phase 1 assessments were not sufficient to demonstrate adequate seismic stability for the Sluice Trench and Ballfield East of Sluice Trench. A Phase 2 assessment, including collection of additional information from a Phase 2 Exploratory Drilling effort, was performed to evaluate seismic stability for the Sluice Trench and Ballfield East of Sluice Trench.

Details of the analyses performed are presented in the sections below. Graphical stability analysis results are included in Appendix B (global stability) and Appendix C (veneer stability). Supporting information for the seismic stability analyses is included in Appendix D. Supplemental information for characterizing soil parameters and common seismic procedures are included in Appendix E and Appendix F, respectively.

3.0 PHYSICAL SETTING AND SITE HISTORY

3.1 EXISTING CONDITIONS

The Sluice Trench and Ballfield East of Sluice Trench (Figure 1) was capped and closed in 2019. The unit is located along the Emory River, near the intake for the plant. The unit includes a clay embankment dike known as the East Dike, the water quality channel, and a portion of the Polishing Pond. The East Dike forms the southeastern perimeter of the unit. The Engineered Wetlands area is outside the limits of the CCR unit. With respect to the stability of this CCR unit, the focus is on slope failures along the East Dike that could result in a release of CCR to the adjacent river/intake channel.

Figure 1. Sluice Trench and Ballfield East of Sluice Trench, showing East Dike Location

3.2 GEOLOGIC SETTING

The KIF Plant is situated on the western edge of the Valley and Ridge Physiographic province near the base of the Cumberland Plateau. Numerous faults, trending northeast to southwest as characteristic of the Valley and Ridge Province, are depicted on the geologic mapping. The plant is positioned between the Chattanooga Fault to the north, and the Kingston Fault to the south.

According to the United States Geological Survey Geologic Map of the Harriman Quadrangle (Moore, Finlayson, and Milici 1993), the plant is underlain by Lower Ordovician and Cambrian age limestone and shale bedrock formations. Although not depicted on the geologic mapping, previous drilling programs at the plant indicate that alluvial deposits consisting of fine sands, silty sands and sandy silts are present at the plant, as are commonly found adjacent to rivers.

The majority of the plant, including the Sluice Trench and Ballfield East of Sluice Trench, is underlain by the Conasauga Shale Formation, which consists of an argillaceous to silty shale with zones of shaley limestone scattered throughout. The geologic mapping indicates this formation is contorted, brecciated, and sheared throughout. The geologic mapping indicates Pine Ridge, just north of the plant, and the northern corner of the Kingston Recovery Project (KRP) Ash Landfill are underlain by the Rome Formation, consisting of arenaceous shale interbedded with very thin siltstone layers and thin beds of sandstone.

3.3 SITE HISTORY

TVA constructed the KIF Plant from 1951 to 1954 and commenced operations in 1954. In 1956, the East Dike was constructed as part of the initial ash disposal area, which includes the footprints of the present-day Sluice Trench and Ballfield East of Sluice Trench and the Interim Ash Staging Area. Construction of the perimeter containment dikes around the former main ash pond were completed in 1958.

The sluice trench was constructed in the late 1960s along the east portion of the initial ash disposal area. The sluice trench was used to sluice ash from the plant to the former main ash pond, which is now within the footprint of the KRP Ash Landfill (Calvert 1967 and 1968). Historical annual inspections (Parrish 1970) reported that the ash was generally sluiced quickly enough from the plant to the main ash pond such that there was minimal ash deposition in the sluice trench.

As part of the KRP, CCR was temporarily staged at the sluice trench and the Interim Ash Staging Area. The staged ash was removed in 2015, and as part of the closure a low permeability soil cap was constructed. The closure design of the Interim Ash Staging Area (AECOM 2016a, 2016b, and 2016c) generally leveled the site to conform to the higher surrounding grades, with gentle slopes (3 percent [%] maximum) and small perimeter ditches to promote surface drainage.

In 2015, as part of the cap construction for the Sluice Trench unit, the sluice trench was filled in and a new Water Quality Channel was constructed to the southeast along a parallel alignment. The Water Quality Channel was lined with a geomembrane and designed to convey process water to the Stilling Pond (TVA 2015). During the subsequent Polishing Pond construction, the Water Quality Channel was rerouted to convey the process water to the Polishing Pond.

The Polishing Pond was constructed in 2017 over a segment of the former sluice trench and a portion of the Ballfield East of Sluice Trench. The area was partially excavated and geosynthetic clay liner and a geomembrane were placed over the area within the limits of the Polishing Pond. Outside the limits of the Polishing Pond, a soil cap was constructed over another segment of the former Sluice Trench and another portion of the Ballfield East of Sluice Trench (AECOM 2016b).

CCR excavated during the closure of the Interim Ash Staging Area, sluice trench, and construction of the water quality channel and Polishing Pond was placed in the KRP Ash Landfill.

In 2018, a reverse graded filter and seepage collection system was constructed along the outboard face of the East Dike, as part of a seepage mitigation project (AECOM 2018). The filter and collection system were constructed to mitigate concerns from historical seeps observed along the outboard face of the dike.

In 2019, the last remaining uncapped portion of the Ballfield East of Sluice Trench was regraded and capped with a geomembrane and vegetative soil layer. As part of the regrading effort for the area, a heterogenous mix of CCR and soil was placed as structural fill to prepare the subgrade prior to constructing the cover system. This East Dike Area Closure project (AECOM 2019) capped the corridor between the East Dike and the areas that were already capped as part of the Water Quality Channel and Polishing Pond projects.

3.4 PRIOR SUBSURFACE INVESTIGATIONS

Historical boring and geotechnical data were used to supplement data collected during execution of the Exploratory Drilling, Hydrogeological Investigation, and Background Soil SAPs. The Phase 2 seismic stability assessment for the Sluice Trench and Ballfield East of Sluice Trench utilized information from the Phase 1 and Phase 2 Exploratory Drilling programs.

The prior subsurface investigations used to support the stability analysis of the Sluice Trench and Ballfield East of Sluice Trench include:

- Stantec (2009) – historical boring logs within the Engineered Wetlands adjacent to the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of the foundation soil subunits
- MACTEC (2009) – historical boring logs and laboratory testing from borings along the East Dike at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of the CCR and foundation soil subunits
- Geosyntec (2010a) – historical boring logs and laboratory testing from borings along the East Dike at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of the CCR, embankment dike material, and foundation soil subunits
- Geosyntec (2010b) – historical boring logs and laboratory testing from borings along the East Dike at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of the foundation soil subunits

- Geosyntec (2012) – historical boring logs and laboratory testing from borings along the East Dike at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of the CCR, embankment dike material, and foundation soil subunits
- AECOM (2016a) – historical boring logs and laboratory testing of soils from borings at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of CCR, embankment dike material, and foundation soil subunits
- AECOM (2016b) – historical boring logs, laboratory testing of soils from borings, and cone penetration test (CPT) soundings at the Sluice Trench and Ballfield East of Sluice Trench were used to characterize the strengths and index properties of CCR, embankment dike material, and foundation soil subunits
- Stantec (2017) – historical boring logs and laboratory testing were used to characterize the strengths and index properties of the foundation soil subunits.

3.5 PRIOR STABILITY ANALYSES

Prior stability analyses, which were reviewed when developing/updating stability models, for the Sluice Trench and Ballfield East of Sluice Trench include the following:

- Geosyntec (2010a): Static long-term global slope stability analysis of the East Dike
- Geosyntec (2010b): Static long-term and seismic (pseudostatic) short-term global slope stability analyses of the East Dike
- Geosyntec (2012): Static long-term global slope stability analysis of the East Dike, incorporating results of additional geotechnical exploration
- AECOM (2016b): Static long-term and seismic (pseudostatic and post-earthquake) short-term global stability analyses of the East Dike and Polishing Pond, incorporating results of additional geotechnical exploration.

The historical analyses of the Drainage and Flow Management Project (i.e., Polishing Pond and Water Quality Channel) constructed within the Sluice Trench and Ballfield East of Sluice Trench unit (AECOM 2016a, 2016b) do not include veneer stability analyses for seismic conditions. Further, these available analyses did not include geometry changes from recent construction of a graded filter and seepage collection system along the outboard slope of the East Dike (AECOM 2017) or from recent closure (regrading and capping) of the East Dike Area (AECOM 2019). Therefore, new seismic (global and veneer) stability analyses and liquefaction triggering analyses for the existing (with graded filter and East Dike Area closure) conditions were performed. These analyses were performed in accordance with the Stability SAP.

4.0 SUBSURFACE CHARACTERIZATION

4.1 MATERIAL PROPERTIES

Subsurface materials are identified based on the project records, subsurface explorations, laboratory testing, and other available information. A material is a region or zone in the analytical model comprised of an idealized grouping of soil or rock sublayers of similar geologic origin or geotechnical behavior, subject to practical considerations in the analysis. A material is not necessarily a single type of soil or rock and may include significant variability. Field information may identify sub-layers or sub-units within a given material. The key materials (i.e., idealized groupings for characterization) for purposes of seepage and/or stability analyses are represented in Table 2, with the CCR units where the material is located and a brief description. Material delineation/zonation considered the potential for weak or otherwise distinct strata that may affect the seismic stability analyses. Such strata were modeled as separate materials, if/when appropriate. Physical properties of these materials are described in the subsections below. For context, the selected material parameters are compared to those used in historical analyses (where available, and for information only). For the shale bedrock, relevant material properties are described separately in subsections 4.1.9 and 4.1.10.

Table 2. Identification of Subsurface Materials at KIF Plant

Material Name	CCR Units	Description
Embankment Fill	Sluice Trench and Ballfield East of Sluice Trench	Compacted clay fill including the starter dike
Fly Ash	Sluice Trench and Ballfield East of Sluice Trench	Fly ash sluiced into the initial ash storage area
Bottom Ash	Sluice Trench and Ballfield East of Sluice Trench	Bottom ash sluiced (early operations) or placed and compacted (later operations); sometimes used as structural fill
Cover Material	Sluice Trench and Ballfield East of Sluice Trench	Compacted soil fill at the surface of the capped portions of the unit
Filter Materials	Sluice Trench and Ballfield East of Sluice Trench	American Society for Testing and Materials (ASTM) C33 concrete sand and Tennessee Department of Transportation (TDOT) No. 78 stone; part of 2018 reverse graded filter on East Dike outboard slope
Riprap	Sluice Trench and Ballfield East of Sluice Trench	TDOT A1 Riprap; part of 2018 reverse graded filter on East Dike outboard slope
Sediment	Sluice Trench and Ballfield East of Sluice Trench	Natural, alluvial sandy silt to clay sediment deposited in the intake channel after the East Dike was built
Foundation Soil - Subunit 1 (Subunit 1)	Sluice Trench and Ballfield East of Sluice Trench	Natural, alluvial deposits of lean clay to silty lean clay soil
Foundation Soil - Subunit 2 (Subunit 2)	Sluice Trench and Ballfield East of Sluice Trench	Natural, alluvial deposits of silty sand to sandy silt, with no less than about 30% fines
Foundation Soil - Subunit 3 (Subunit 3)	Sluice Trench and Ballfield East of Sluice Trench	Natural, alluvial deposits of sand to silty sand, with less than about 30% fines
Gravel Residuum	Sluice Trench and Ballfield East of Sluice Trench	Natural, silty sand with gravel; Residual soil above bedrock
Shale[1]	Sluice Trench and Ballfield East of Sluice Trench	Weathered shale bedrock, with dipping beds and occasional layers of limestone

Notes:

1. For the shale bedrock, relevant material properties are described separately in subsections 4.1.9 and 4.1.10.

4.1.1 General Description and Geologic Origin

4.1.1.1 Embankment Fill

The Embankment Fill is generally described as a silty clay material with some shale fragments, as encountered during historical exploration. The Embankment Fill material was placed during the original construction of the East Dike at the perimeter of the initial ash disposal area, along the KIF Plant intake channel. Record drawings specify that the material should “be fine and relatively impervious,” and that “select firm shale material be placed below the water level” for a portion of the East Dike (TVA 1956). The Embankment Fill extends up to 29 feet (ft) in thickness along the crest of the original alignment of the East Dike.

In previous stability analyses (Geosyntec 2010a 2012) the Embankment Fill was modeled as two zones, an upper and lower dike fill. The delineation of the zones correlates to a decrease in the Standard Penetration Test (SPT) blowcounts (i.e., N-values). The delineation of the Embankment Fill was reevaluated as part of this study. The higher blowcounts were attributed to suction-induced strength above the phreatic surface. Otherwise, the upper and lower dike fill materials were similar in type and behavior. Therefore, the material was modeled as one material rather than two.

4.1.1.2 Fly Ash

The Fly Ash material is composed primarily of fine-grained CCR that is generally described as a non-plastic, sandy silt. The Fly Ash was sluiced into the initial ash disposal area, during early operations of the plant. The thickness ranges from 4 ft adjacent to the Embankment Fill to 15 ft in the interior of the Ballfield East of Sluice Trench.

4.1.1.3 Bottom Ash

The Bottom Ash material is composed primarily of coarse-grained CCR that is generally described as a silty sand to sandy silt. The Bottom Ash was placed during operation of the sluice trench in the Ballfield East of Sluice Trench, over the Fly Ash material. Some bottom ash was sluiced, while some was placed and compacted. Bottom Ash was sometimes used as structural fill, such as in the Polishing Pond perimeter dike. In some instances, bottom ash used as structural fill may contain some fraction of random soil fill. The Bottom Ash is up to 35 ft thick in the interior of the Ballfield East of Sluice Trench.

4.1.1.4 Cover Material

The Cover Material was placed during the closure of the Sluice Trench and Ballfield East of Sluice Trench as part of the engineered soil cap. The soil was sourced from the “I-40 borrow area”, as detailed in the construction certification report for the closure of the unit (AECOM 2019). Per the closure documentation (AECOM 2019), the cap system consists of 24 inches of protective cover soil, overlying a geocomposite drainage layer (geotextile/geonet/geotextile) and geomembrane (textured 60-mil Linear Low-Density Polyethylene [LLDPE]), overlying the CCR material. The geosynthetics were characterized using the typical properties from their respective manufacture product sheets (AGRU 2018 and SKAPS 2017) because no project-specific testing was available.

4.1.1.5 Filter Materials

The Filter Materials include ASTM C33 sand and TDOT No. 78 stone used in the reverse-graded filter constructed as part of the Seepage and Drainage repair along the East Dike (AECOM 2017). In this analysis, it was adequate to model the ASTM C33 sand and TDOT No. 78 stone as one material. The Filter Materials were sourced from the Rogers Roane County Quarry in Harriman, Tennessee (AECOM 2018). The thickness of the Filter Materials varies from two ft up to 3.5 ft along the outboard face of the East Dike.

4.1.1.6 Riprap

The Riprap consists of TDOT A1 Riprap placed as part of the Seepage and Drainage repair along the East Dike (AECOM 2017). The Riprap was sourced from the Rogers Roane County Quarry in Harriman, Tennessee (AECOM 2018). The Riprap was placed in a two-foot-thick layer over the Filter Materials along the outboard face of the East Dike.

4.1.1.7 Sediment

The Sediment material is a recent deposit that has accumulated since the East Dike was built. It was encountered along the bottom of the intake channel and against the outboard toe of the East Dike. The material is very loose, with typical blowcount values less than one (i.e., weight of SPT hammer or weight of drill rods). It is generally described as an alluvial sandy silt or clay. The Sediment is approximately 6 ft thick at the outboard toe of the East Dike, and extends into the intake channel, tapering to one foot or less in thickness.

4.1.1.8 Foundation Soils

The foundation soils underlying the site were generally more fine-grained and plastic near the original ground surface and transitioned to a sandier, non-plastic material at greater depths, until bedrock was encountered. The transition between the materials was gradual and, although distinct horizon delineations were not noted, the foundation was divided into three subunits using the criteria listed in the subsections below. The varying presence of the uppermost foundation soil (Subunit 1) has been attributed to the alluvial deposition of the foundation soils.

4.1.1.7.1 Subunit 1

Subunit 1 is generally described as an alluvial, silty, lean clay deposit that comprises the upper portions of the alluvial foundation along the Emory River and intake channel, extending into the interior of the Sluice Trench and Ballfield East of Sluice Trench. Based on historical and TDEC Order borings, the presence and thickness of this subunit is highly variable across the site. Subunit 1 was not encountered in the vicinity of the Polishing Pond but was encountered under the East Dike closer to the intake channel. Where encountered, the thickness of Subunit 1 varies between approximately five ft at the interior of the Ballfield East of Sluice Trench and approximately 10 ft extending into the intake channel.

4.1.1.7.2 Subunit 2

Subunit 2 is generally described as a sandy silt to silty sand with no less than about 30% fines, comprising part of the alluvial foundation at the Sluice Trench and Ballfield East of Sluice Trench. Subunit 2 is continuous across the unit footprint and underlies Subunit 1 (where present). Where Subunit 1 is not present (e.g., the Polishing Pond), Subunit 2 is the uppermost foundation material. Subunit 2 varies in thickness from approximately five to 15 ft.

4.1.1.7.3 Subunit 3

Subunit 3 is generally described as an alluvial silty sand with less than about 30% fines and comprises the lower foundation. This subunit overlies the shale bedrock and varies in thickness from approximately five to 10 ft.

4.1.1.9 Gravel Residuum

The Gravel Residuum is generally described as a silty sand with gravel. Based on the historical and TDEC Order borings, the presence and thickness of this material is highly variable across the site. The Gravel Residuum was not encountered at Section A-A' but was encountered in one of the intake channel borings at the Polishing Pond Section. This material overlies the shale bedrock and has a thickness of approximately five ft at the encountered location.

4.1.2 Index Properties, Classification, and Density Parameters

The stability analyses require unit weights (densities) for each material or zone that is modeled. Unit weights for each material are summarized in Table 3. These parameters were derived from available laboratory testing results using the methodology outlined in Appendix E. For several materials, the index, classification, and/or density parameters were updated (compared to those used in the KIF Static Stability SAR) to incorporate data from the Phase 2 Exploratory Drilling program. In general, such updates were modest and had little to no impact on the stability analysis results.

Table 3. Density Parameters of the Subsurface Materials at KIF Plant

Material Name	G_s	w (%)	e	γ_d (pcf)	γ_m (pcf)	γ_{sat} (pcf)
Embankment Fill	2.70	22	0.61	105	128	128
Fly Ash	2.51	40	0.96	80	112	112
Bottom Ash	2.67	21	0.68	99	119	124
Cover Material	2.72	30	0.83	92	120	121
Filter Materials	2.77	20	0.65	105	126	130
Riprap	2.65	15	0.65	100	115	125
Sediment	2.70	38	1.11	80	111	113
Subunit 1	2.69	26	0.65	102	127	127
Subunit 2	2.68	22	0.62	103	126	127
Subunit 3	2.74	24	0.61	106	131	131
Gravel Residuum	2.70	15	0.40	120	138	138

Notes:

G_s	Specific Gravity of the solids	γ_d	dry unit weight
w	natural, gravimetric water content	γ_m	moist unit weight
e	void ratio	γ_{sat}	saturated unit weight
%	percent	pcf	pounds per cubic foot

The following subsections detail the available data and basis for selecting the density parameters for each material.

4.1.2.1 Embankment Fill

Historical index testing (AECOM 2016b, Geosyntec 2010a and 2010b) is available to characterize the Embankment Fill. The aggregated historical laboratory testing of the Embankment Fill material produced an average moist unit weight of 128 pounds per cubic foot (pcf), which was selected as the representative moist unit weight for the material. A dry unit weight of 104 pcf was calculated based on the average moist unit weight and moisture content values. The Embankment Fill generally classified per ASTM D2487: *Standard Practice for Classification of Soils for Engineering Purposes (Unified Soil Classification System [USCS])* as a sandy, lean clay (CL) to silty sand (SM). The averages of the historical laboratory testing results were also used as the representative void ratio and specific gravity values (0.61 and 2.70, respectively). The median fines content and average moisture content of the Embankment Fill material were 42% and 22%, respectively. The median fines content was selected due to outliers skewing the average fines content of the material.

The selected values are within the expected range for the material. See Appendix E for additional discussion of typical values. The values are also similar to those used in previous analyses. The supplemental assessment by Geosyntec (2012) used moist unit weights of 125 and 120 pcf for the Upper Dike Fill and Lower Dike Fill, respectively. The unit weight used in the historical analysis by AECOM (2016b) is 132 pcf, for their “Fill: Sandy Silt”, which is analogous to the Embankment Fill.

4.1.2.2 Fly Ash

The Fly Ash material was characterized using data from the Exploratory Drilling SAR and historical index testing (Geosyntec 2010a and 2010b, AECOM 2016b, and MACTEC 2009). Generally, average values from the recent and historical laboratory data were selected for use in the analyses. The Fly Ash material generally classified per USCS as a non-plastic, sandy silt (ML) and had an average fines content of 57% and average moisture content of 40%.

The average moist unit weight was 112 pcf. A dry unit weight of 80 pcf was calculated based on the average moist unit weight and moisture content values. The average void ratio and specific gravity from current and historical laboratory testing were also selected as the representative values (0.96 and 2.51, respectively).

The total unit weight for the Fly Ash is similar to the unit weight used in the latest stability from the Polishing Pond Report (AECOM 2016b) of 117 pcf. The Polishing Pond Report modeled the Fly Ash and Bottom Ash as a single material, Ash Fill. The average of the Fly Ash and Bottom Ash unit weights selected for this analysis is equal to the value used for the Ash Fill in the Polishing Pond assessment (AECOM 2016b). The Seepage and Stability Study for the East Dike (Geosyntec 2010a) and Supplemental Assessment of Seepage and Slope Stability (Geosyntec 2012) used a total unit weight of 75 pcf based on recommended values from previous analyses completed at the KIF Plant.

4.1.2.3 Bottom Ash

The Bottom Ash material was characterized using data from the Exploratory Drilling SAR and historical index testing (Geosyntec 2010a and 2010b, AECOM 2016b, and MACTEC 2009). Generally, average values from the recent and historical laboratory data were selected for use in the analyses. The Bottom Ash material generally classified per USCS as a SM to sandy silt (ML) and had an average fines content of 32% and average moisture content of 21%. The average moist unit weight was 119 pcf. The representative dry unit weight (99 pcf) was calculated based on the selected moist unit weight and moisture content values. The selected void ratio and specific gravity values for the Bottom Ash were also based on averages from laboratory data (0.68 and 2.67, respectively).

The selected moist unit weight for the Bottom Ash material is similar to the value (117 pcf) used for the "Ash Fill" materials in the Polishing Pond Engineering Report (AECOM 2016b). The Bottom Ash and Fly Ash were modeled as one material (Ash Fill) by AECOM. If the unit weights assigned herein to the Bottom Ash and the Fly Ash are averaged, the result is equivalent to the unit weight of the previous Ash Fill. Other historical analyses assumed a lower value (100 pcf) based on limited data.

4.1.2.4 Cover Material

The Cover Material generally classified as a fat clay with sand and was sourced from a borrow area offsite (I-40, Exit 364). Selected parameters for the Cover Material are based on the construction closure record document (AECOM 2019) for the Sluice Trench and Ballfield East of Sluice Trench. The moist unit weight selected was the average from seven proctor tests performed on seven bulk samples from the borrow site. The void ratio and moisture content were selected based on typical values (Appendix E).

4.1.2.5 Filter Materials

The Filter Materials include ASTM C33 sand and TDOT No. 78 stone (AECOM 2017) used to construct the reverse-graded filter along the East Dike. Properties for the Filter Materials in Table 3 were estimated using typical values.

4.1.2.6 Riprap

The Riprap consists of TDOT A1 Riprap (AECOM 2017). Properties for the Riprap in Table 3 were estimated using typical values.

4.1.2.7 Sediment

The Sediment material was characterized using data from the Exploratory Drilling SAR. The Sediment material classified per USCS laboratory testing as a CL. Unit weight testing data was not available for the Sediment. The selected dry unit weight (80 pcf) was estimated using typical values (NAVFAC 1986). The moist unit weight (111 pcf) was calculated using the selected dry unit weight value and the average moisture content from laboratory testing. The void ratio (1.11) was calculated using the selected dry unit weight and an estimated specific gravity value (2.70).

4.1.2.8 Subunit 1

The Subunit 1 material is comprised of alluvial, plastic, fine-grained soil that classifies per USCS laboratory testing as CL. The soil was characterized using data from the Exploratory Drilling SAR and historical index testing (Geosyntec 2010a and 2010b). Generally, average values from the recent and historical laboratory data were selected for use in the analyses. The Subunit 1 material had an average fines content of 81% and average moisture content of 26%.

The average moist unit weight was 127 pcf. The selected dry unit weight (102 pcf) was calculated using the selected moist unit weight and moisture content values. From the current and historical laboratory testing, the average void ratio and specific gravity were also selected as the representative values (0.65 and 2.69, respectively).

The moist unit weight for Subunit 1 is similar to that used in historical analyses. The Seepage and Stability Study for the East Dike (Geosyntec 2010a) and Supplemental Assessment of Seepage and Slope Stability (Geosyntec 2012) used a value of 125 pcf. The Polishing Pond Analysis, which modeled the foundation soil as a single unit, used a value of 117 pcf (AECOM 2016b). The selected moist unit weight for Subunit 1 is also similar to the value (125 pcf) used in the Stilling Pond Analysis (Stantec 2020).

4.1.2.9 Subunit 2

Subunit 2 consists of alluvial deposits classified per USCS laboratory testing as SM to ML with fines content no less than about 30%. Historical index testing (Geosyntec 2010a and 2010b, MACTEC 2009, and AECOM 2016b) from various analyses and subsurface explorations was used to characterize the soil. The Subunit 2 material had an average fines content of 46% and average moisture content of 22%.

The average moist unit weight was 126 pcf. The selected dry unit weight (103 pcf) was calculated using the selected moist unit weight and moisture content values. The average void ratio and specific gravity from historical laboratory testing were selected as the representative values (0.62 and 2.68, respectively).

The moist unit weight for Subunit 2 is similar to the unit weights used in historical stability analyses. The Seepage and Stability Study for the East Dike (Geosyntec 2010a) and Supplemental Assessment of Seepage and Slope Stability (Geosyntec 2012) used a value of 125 pcf. The Polishing Pond Analysis, which modeled the foundation soil as a single unit, used a value of 117 pcf (AECOM 2016b). The moist unit weight assigned to Subunit 2 is similar to the value (125 pcf) used in the KIF Plant Stilling Pond Stability Analysis (Stantec 2020).

4.1.2.10 Subunit 3

Subunit 3 consists of alluvial deposits classified per USCS laboratory testing as SM to ML with fines content of less than about 30%. Historical index testing (Geosyntec 2010a and 2010b, AECOM 2016b) from various analyses and subsurface explorations was used to characterize the soil. The Subunit 3 material had an average fines content of 22% and average moisture content of 24%.

The average moist unit weight was 131 pcf. The selected dry unit weight (106 pcf) was calculated using the selected moist unit weight and moisture content values. The average void ratio and specific gravity from historical laboratory testing were selected as the representative values (0.61 and 2.74, respectively).

The selected moist unit weight for Subunit 3 is higher than the unit weights used in historical stability analyses. The Seepage and Stability Study for the East Dike (Geosyntec 2010a) and Supplemental Assessment of Seepage and Slope Stability (Geosyntec 2012) used a value of 120 pcf. The Polishing Pond Analysis, which modeled the foundation soil as a single unit, used a value of 117 pcf (AECOM 2016b). The moist unit weight assigned to Subunit 3 for the KIF Plant Stilling Pond Stability Analysis is 127 pcf (Stantec 2020).

4.1.2.11 Gravel Residuum

The Gravel Residuum was characterized using data from the Exploratory Drilling SAR. The material classified per USCS laboratory testing as a SM with gravel and fines content of 37% and 18%, respectively.

The selected dry unit weight (120 pcf) was estimated using typical values (NAVFAC 1986). The moist unit weight (138 pcf) was calculated using the selected dry unit weight value and the average moisture content from laboratory testing. The void ratio (0.40) was calculated using the selected dry unit weight and an estimated specific gravity value (2.70).

4.1.3 Small-Strain Shear Stiffness

The range of values for the small-strain shear stiffness parameters are summarized in Table 4. As detailed in Appendix E, small-strain stiffness can be measured or characterized in terms of shear wave velocity (V_s) or small-strain shear modulus (G_{max}). G_{max} was calculated using Equation 1 in Appendix E. The mass densities listed correspond to the unit weights in Table 3.

The values presented in Table 4 are a generic representation and were not directly used in the seismic ground response analyses. Instead, stiffness parameters were modified on a section/profile basis based on the available boring data (i.e., seismic CPT (SCPTu), compression wave-shear wave (P-S) suspension logging). Where certain materials lack section/profile specific V_s data, typical values within the ranges in Table 4 may be used as applicable. See Appendix E for additional information.

Table 4. Small-Strain Shear Stiffness Parameters of the Subsurface Materials at KIF Plant

Material Name	Total[1] Unit Weight γ_t (pcf)	Mass Density ρ_t (slugs/ft^3)	Selected Shear Wave Velocity V_s (ft/sec)	Range in Shear Wave Velocity V_s (ft/sec)	Range in Small-Strain Shear Modulus G_{max} (psf)
Embankment Fill	128	3.98	1,100	790 – 1,298	2.48E+06 – 6.70E+06
Fly Ash	112	3.48	725	443 – 1,681	6.95E+05 – 9.83E+06
Bottom Ash	124	3.85	650	516 – 1,000	1.03E+06 – 3.88E+06
Cover Material	120	3.73	—	294 – 383	3.21E+05 – 5.51E+05
Filter Materials	126	3.92	—	435 – 524	7.42E+05 – 1.07E+06
Riprap	115	3.57	—	289 – 380	2.98E+05 – 5.17E+05
Sediment	113	3.44	260	197 – 363	1.34E+05 – 4.53E+05
Subunit 1	127	3.95	750	545 – 1,599	1.17E+06 – 1.01E+07
Subunit 2	127	3.95	700	558 – 1,849	1.23E+06 – 1.34E+07
Subunit 3	132	4.10	700	559 – 2,236	1.28E+06 – 2.05E+07
Gravel Residuum	138	4.30	770	752 – 788	2.43E+06 – 2.67E+06

Notes:

pcf	pounds per cubic foot	psf	pounds per square foot
slugs/ft^3	slugs per cubic foot	ft/sec	feet per second
V_S	shear wave velocity	G_{max}	small-strain shear modulus
γ_t	total unit weight	ρ_t	mass density

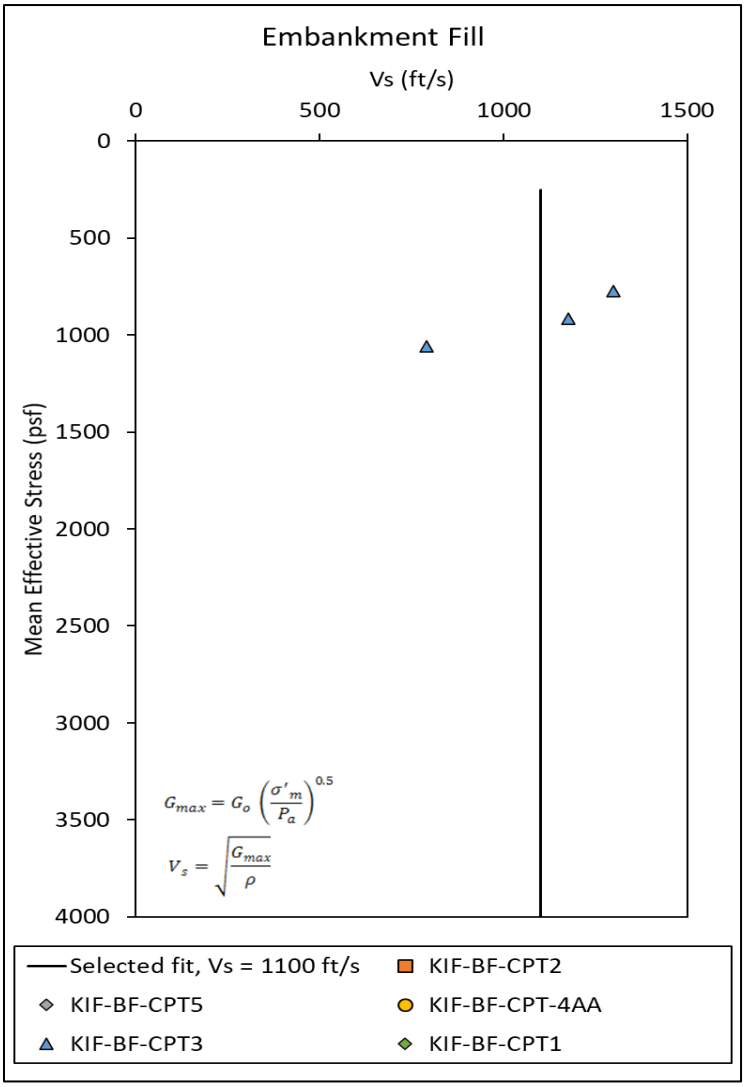
1. Equal to moist unit weight in unsaturated materials or saturated unit weight in saturated materials

The following subsections detail the available data and basis for selecting the small-strain stiffness parameters for each material.

4.1.3.1 Embankment Fill

The measured shear wave velocities within the Embankment Fill were obtained from the 2016 SCPTu soundings (AECOM 2016b). The average V_s of the Embankment Fill was selected as the representative V_s for the material (1,100 ft/sec), as shown on Figure 2.

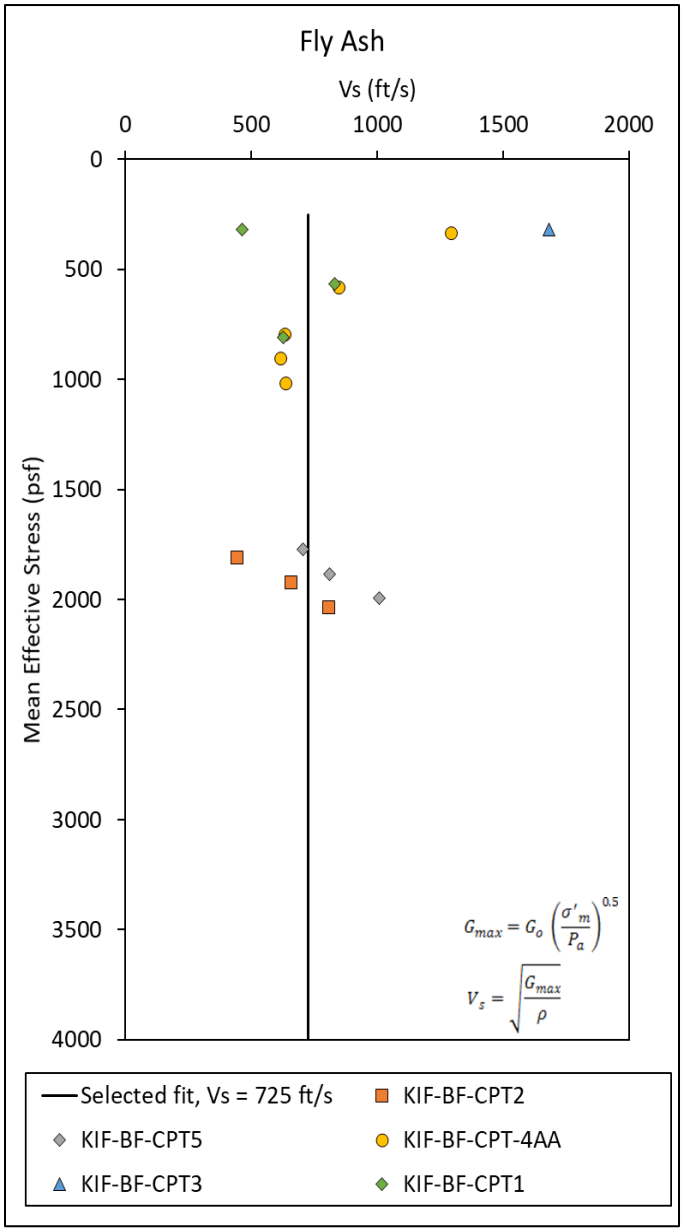
Figure 2. Measured Shear Wave Velocity versus Mean Effective Stress in Embankment Fill and Selected Fit Line



4.1.3.2 Fly Ash

The measured shear wave velocities within the Fly Ash were obtained from the 2016 SCPTu soundings (AECOM 2016b). The median V_s was selected as the representative V_s for the Fly Ash (725 ft/sec), as shown on Figure 3. The median value was selected instead of the average value due to the nature of the scatter in the plot.

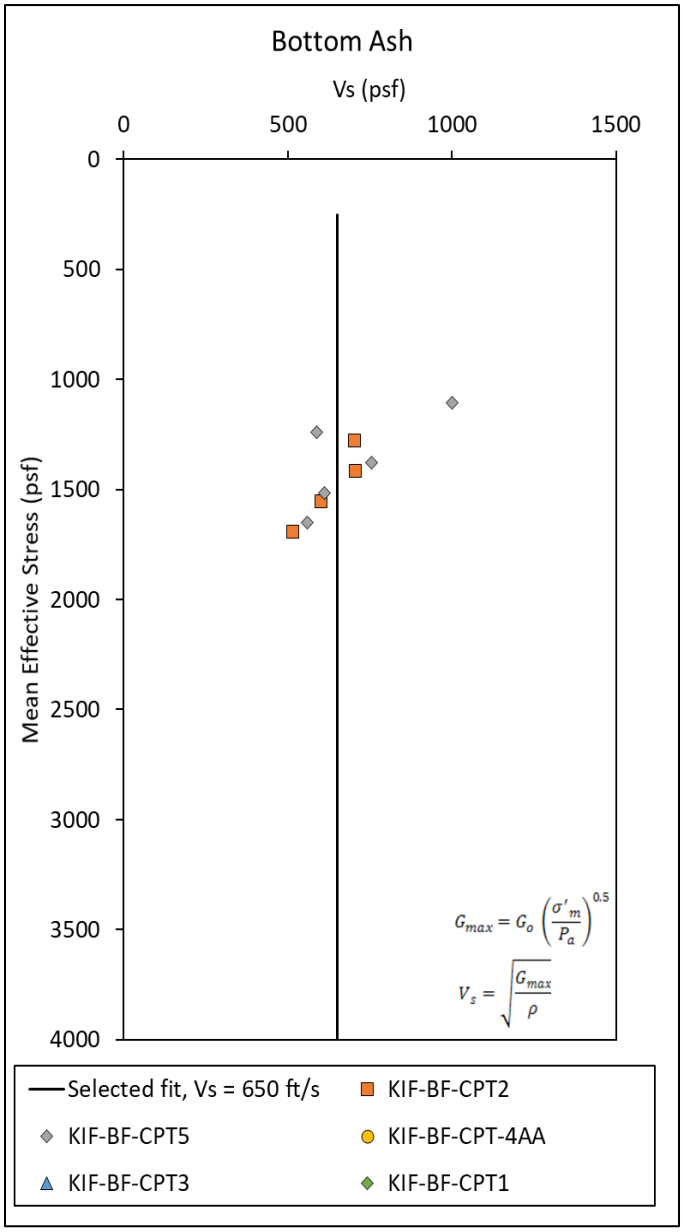
Figure 3. Measured Shear Wave Velocity versus Mean Effective Stress in Fly Ash and Selected Fit Line



4.1.3.3 Bottom Ash

The measured shear wave velocities within the Bottom Ash were obtained from the 2016 SCPTu soundings (AECOM 2016b). The average V_s was selected as the representative V_s for the Bottom Ash (650 ft/sec), as shown on Figure 4.

Figure 4. Measured Shear Wave Velocity versus Mean Effective Stress in Bottom Ash and Selected Fit Line



4.1.3.4 Cover Material

The shear modulus for the Cover Material was determined by using the general Hardin (1978) correlation, shown in Equation 13 in Appendix E. The over consolidation ratio for the soil was assumed to be 2.0 because the Cover Material was compacted when placed. The V_s was calculated using the correlation for G_{max} in soil at small strains where it is proportional to the square of the V_s of the soil, as shown in Equation 11 of Appendix E. The range for the Cover Material's shear modulus is due to the varying depth

of the phreatic surface within the material, resulting in variation of the stress at the midpoint of the material depth.

4.1.3.5 Filter Materials

The G_{max} for the Filter Materials was calculated using the correlation proposed by Seed and Idriss (1970) for sand, as shown in Equation 12 (Appendix E). The range for the Filter Materials' G_{max} is due to variation in the thickness of material, resulting in variation of the stress at the midpoint of the material depth.

4.1.3.6 Riprap

The G_{max} for the Riprap was calculated using the correlation proposed by Seed and Idriss (1970) for sand, as shown in Equation 12 (Appendix E). The range for the Riprap's G_{max} is due to the varying depth of the phreatic surface within the material, resulting in variation of the stress at the midpoint of the material depth.

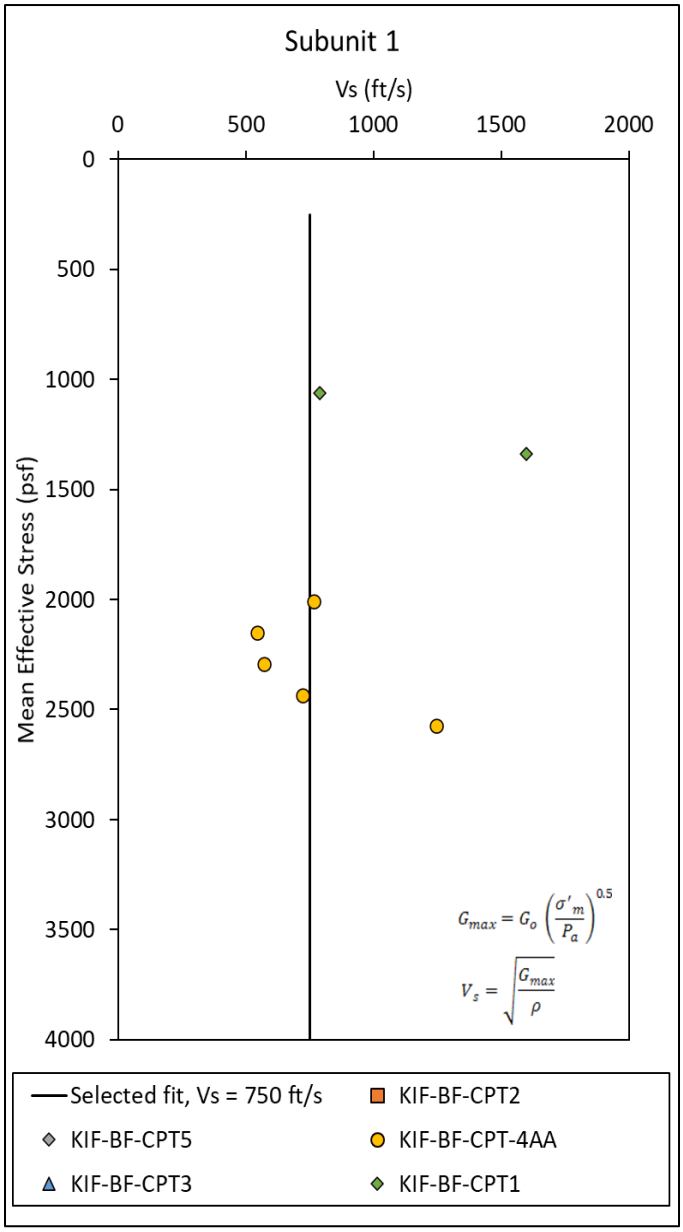
4.1.3.7 Sediment

The G_{max} for the Sediment was calculated using the correlation proposed by Hardin (1978), as shown in Equation 13 (Appendix E). The range of the Sediment's G_{max} is due to the varying thickness of the material, resulting in a variation of the stress at the midpoint of the material. The over consolidation ratio for the material was assumed to be 1.0 because the Sediment was recently deposited (i.e., normally consolidated). The average V_s from the correlation was selected as the representative V_s value for the Sediment (260 ft/sec).

4.1.3.8 Subunit 1

The measured V_s within Subunit 1 were obtained from the 2016 SCPTu soundings (AECOM 2016b). The median V_s was selected as the representative V_s for the Subunit 1 (750 ft/sec), as shown on Figure 5. The median value was selected instead of the average value due to the nature of the scatter in the plot. The V_s for Subunit 1 is slightly higher than the value used for the same material in the latest seismic evaluation of the Stilling Pond design at the KIF Plant. The seismic evaluation of the Stilling Pond design at KIF Plant (Stantec 2020) used a V_s of 700 ft/sec.

Figure 5. Measured Shear Wave Velocity versus Mean Effective Stress in Subunit 1 and Selected Fit Line

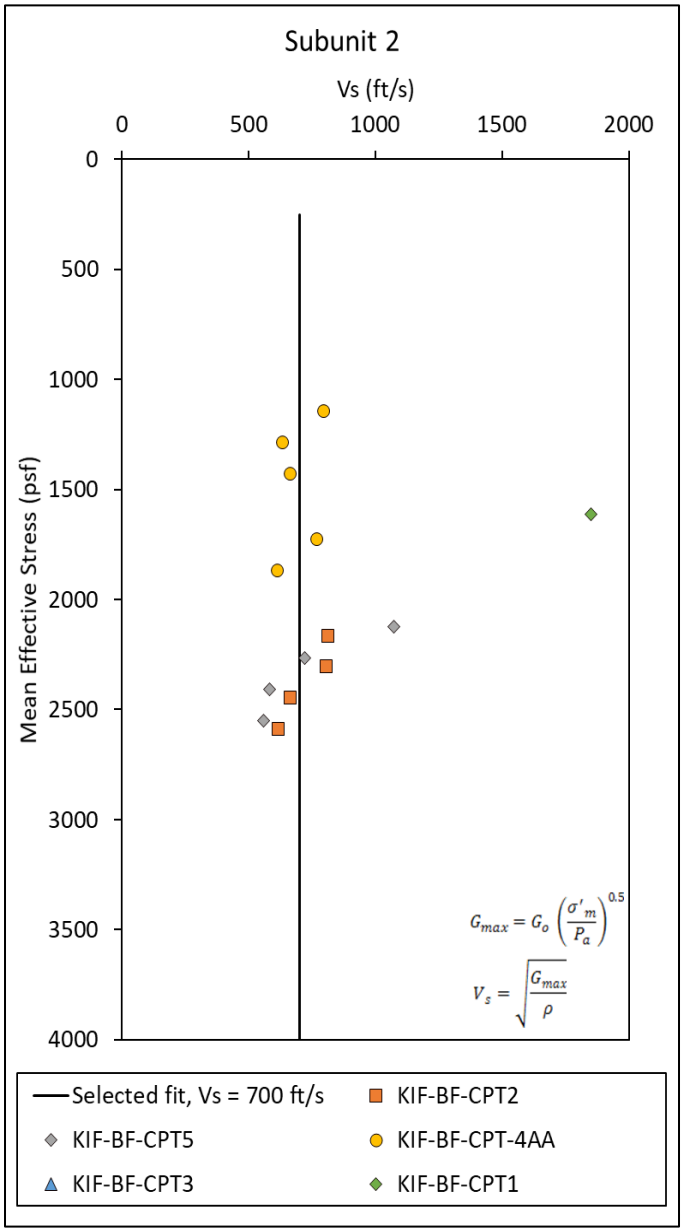


4.1.3.9 Subunit 2

The measured V_s within Subunit 2 were obtained from the 2016 SCPTu soundings (AECOM 2016b). The median V_s was selected as the representative V_s for Subunit 2 (700 ft/sec), as shown on Figure 6. The median value was selected instead of the average due to the nature of the scatter in the plot. The ranges of G_{max} and V_s are similar to the ranges used for these parameters for the Stilling Pond design at the KIF Plant. The seismic evaluation of the Stilling Pond design at KIF Plant (Stantec 2020) developed a site-specific correlation for G_{max} for Subunit 2, in which the ranges for G_{max} are 6.99E+05 to 5.83E+06 psf.

This corresponds to a range of V_s of 424 to 1225 ft/sec, and the representative V_s for the Stilling Pond design is 645 ft/sec.

Figure 6. Measured Shear Wave Velocity versus Mean Effective Stress in Subunit 2 and Selected Fit Line

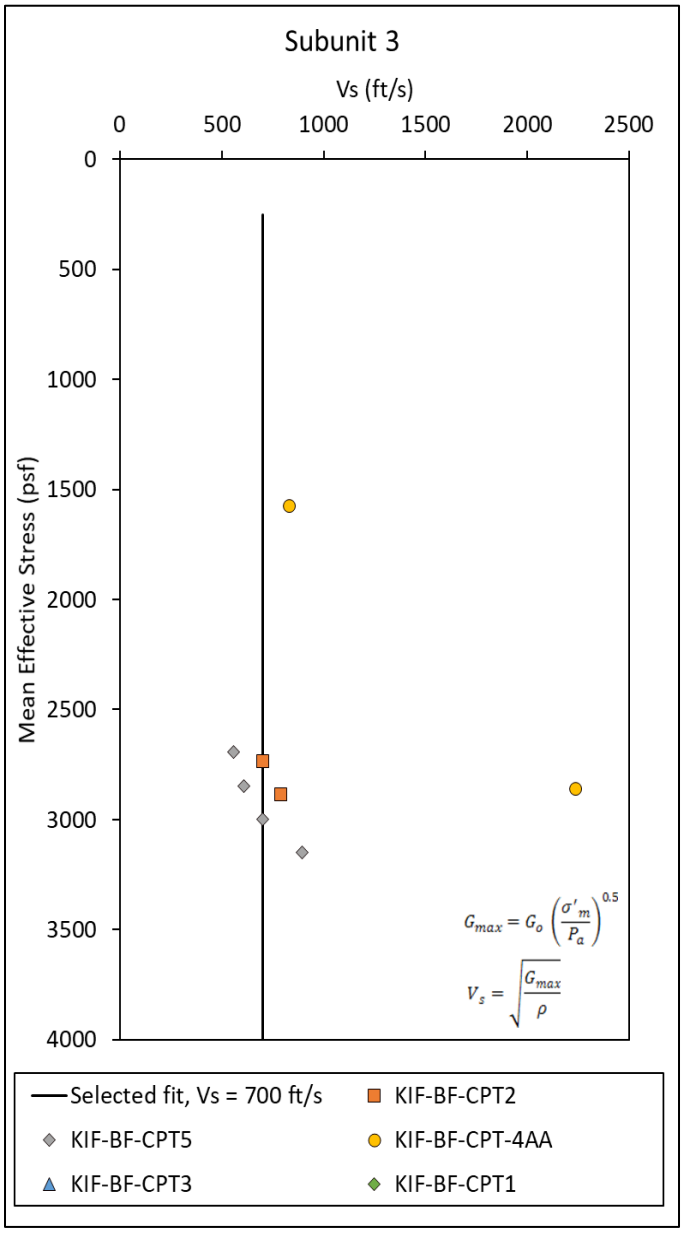


4.1.3.10 Subunit 3

The measured V_s within Subunit 3 were obtained from the 2016 SCPTu soundings (AECOM 2016b). The median V_s was selected as the representative V_s for Subunit 3 (700 ft/sec), as shown on Figure 7. The median value was selected instead of the average value due to the nature of the scatter in the plot. The

V_s for Subunit 3 is similar to the value used for the same material in the latest seismic evaluation of the Stilling Pond design at the KIF Plant. The seismic evaluation of the Stilling Pond design at KIF Plant (Stantec 2020) used a V_s of 670 ft/sec.

Figure 7. Measured Shear Wave Velocity versus Mean Effective Stress in Subunit 3 and Selected Fit Line



4.1.3.11 Gravel Residuum

The G_{max} for the Gravel Residuum was calculated using the correlation proposed by Seed and Idriss (1970) for sand, shown in Equation 12 (Appendix E). The average V_s from the correlations was selected as the representative V_s for the Gravel Residuum (770 ft/sec).

4.1.4 Modulus Degradation and Damping

At shear strains exceeding some small threshold level, soils begin to soften. The softening dynamic response can be represented with shear modulus reduction and damping ratio curves, expressed as functions of the cyclic shear strain (Kramer 1996). Darendeli (2001) developed empirical equations for reduction curves suitable for use in ground response analyses, based on plasticity index (PI), mean effective stress (σ'_m), and cyclic shear strain (γ). The Darendeli (2001) curves were used in these analyses.

The PI of each material is presented in Table 5. These PIs were used to select appropriate modulus reduction and damping curves in *Strata* (ground response analysis software).

Table 5. Plasticity Index used in Empirical Relationships for Modulus Reduction and Damping Ratio of the Subsurface Materials at KIF Plant

Material Name	PI
Embankment Fill	18
Fly Ash	NP
Bottom Ash	NP
Cover Material	38
Filter Materials	NP
Riprap	NP
Sediment	12
Subunit 1	11
Subunit 2	NP
Subunit 3	NP
Gravel Residuum	NP

Notes:

NP Non-plastic

Using the aggregated data from TDEC Order and historical laboratory testing (AECOM 2016b, AECOM 2019, Geosyntec 2010a and 2010b, MACTEC 2009, Stantec 2013), the average PI values were selected as the representative values for each material. For non-plastic materials, a PI of zero was used for shear modulus reduction and selection of the damping curves for the ground response analyses.

4.1.5 Drained Strengths for Static, Long-term Conditions

Drained strength (effective stress) parameters, defined in terms of drained friction angle (ϕ') and drained cohesion (c'), for the subsurface materials under static, long-term conditions are summarized in Table 6. Determination of these drained strengths for the Sediment and the Gravel Residuum (additional materials defined after the Phase 2 Exploratory Drilling) is described in the subsections below. Determination of drained strengths for other materials (unchanged after the Phase 2 Exploratory Drilling) is described in the KIF Static Stability SAR. Background information, typical values, correlations, and measurement methods for characterizing the drained shear strength of soils are discussed in Appendix E. See Section 6.1.8 for discussion on how the drained strengths are applied in the stability model.

Table 6. Drained Shear Strength Parameters for the Analysis of Static, Long-term Conditions, for the Subsurface Materials at KIF Plant

Material Name	ϕ' (deg)	c' (tsf)
Embankment Fill	36	0
Fly Ash	34	0
Bottom Ash	37	0
Cover Material[1]	19	0
Filter Materials	33	0
Riprap	40	0
Sediment	26	0
Subunit 1	32	0
Subunit 2	35	0
Subunit 3	37	0
Gravel Residuum	37	0

Notes:

ϕ'	drained friction angle	c'	drained cohesion
deg	degrees	tsf	tons per square foot

1. To account for possible sliding along the geosynthetic interface within the cap system, the cover system drained strength was assumed to be (φ' = 16º and c' = 0) in the global stability analyses.

4.1.5.1 Sediment

The Sediment is generally composed of very loose, alluvial sediment that classifies as lean clay. The selected drained strength (φ' = 26º and c' = 0) is based on typical values and correlations relating classification and dry unit weight to internal friction angle (NAVFAC 1986), as shown in Appendix E.

4.1.5.2 Gravel Residuum

The Gravel Residuum is generally composed of silty sand with gravel. The Gravel Residuum is assumed to be at least as strong as Subunit 3; thus, it was assigned the same drained strength parameters (φ' = 37º, c' = 0).

4.1.6 Undrained Strengths for Static, Short-Term Conditions

Undrained strength (total stress) parameters, defined in terms of undrained friction angle (ϕ) and undrained cohesion (c), for the subsurface materials under static, short-term conditions are summarized in Table 7. Determination of these parameters for each material is described in the subsections below. Background information, typical values, correlations, and measurement methods for characterizing the undrained shear strength of soils are discussed in Appendix E.

Although the scope of the Stability SAP (Table 1) does not require any static, short-term load cases, the development of undrained strengths for static, short-term conditions is a preliminary step necessary for development of undrained strength for seismic conditions (Section 4.1.7).

In the undrained stability analyses, the contribution of suction pressures to shearing resistance is effectively neglected by specifying composite drained-undrained strength envelopes (Section 6.1.10). The shearing resistance at a given normal stress is then the lesser value of strength computed with the drained or undrained strength parameters (Table 6 and Table 7, respectively).

Table 7. Undrained Shear Strength Parameters for the Analysis of Static, Short-Term Conditions, for the Subsurface Materials at KIF Plant

Material Name	ϕ (deg)	*c* (tsf)
Embankment Fill	11	0.65
Fly Ash	34	0
Bottom Ash	40	0
Cover Material[1]	19	0
Filter Materials	33	0
Riprap	40	0
Subunit 1	21	0.50
Subunit 2	34	0
Subunit 3	34	0
Gravel Residuum	37	0

Notes:

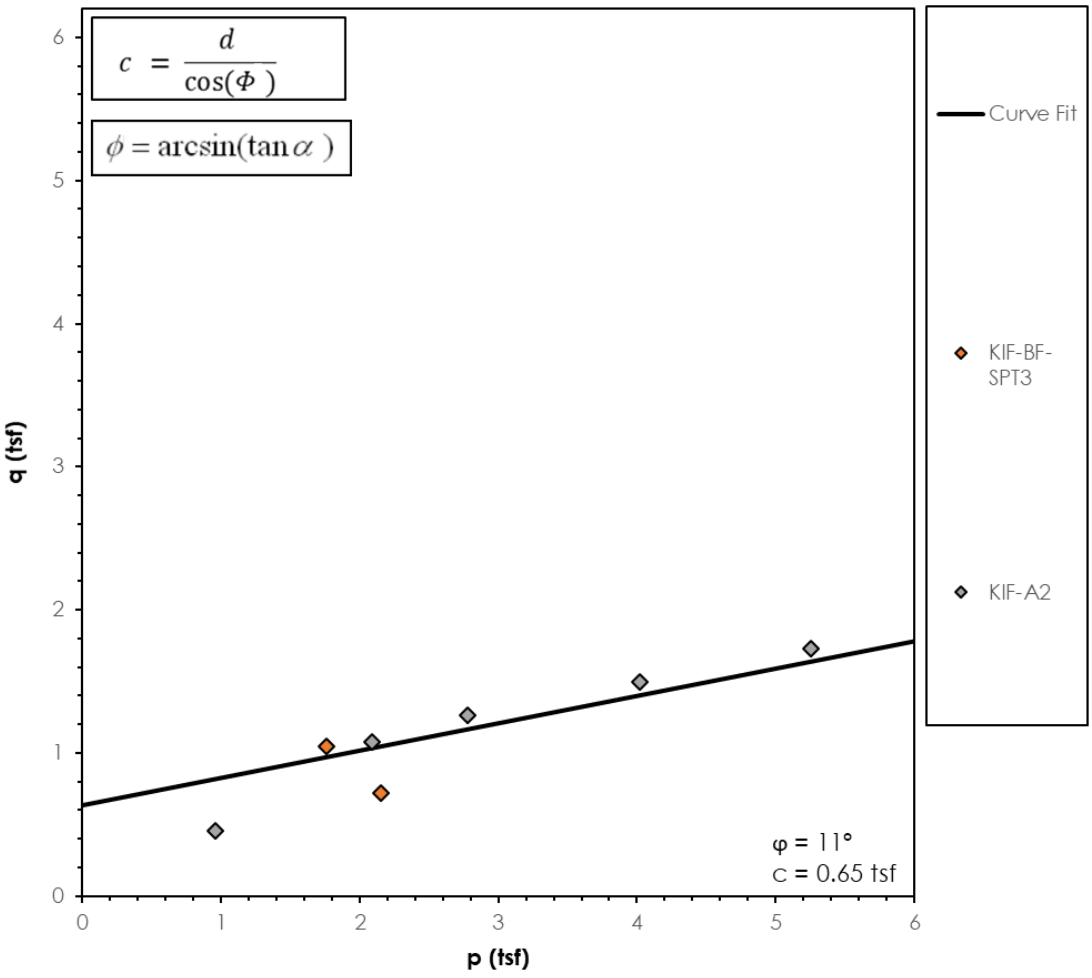
deg degrees tsf tons per square foot

1. To account for possible sliding along the geosynthetic interface within the cap system the cover system undrained strength was assumed to be (φ = 16° and c = 0) in the global stability analyses.

4.1.6.1 Embankment Fill

Undrained strength (total stress) parameters for the Embankment Fill under static, short-term conditions are presented on Figure 8. Determination of these parameters is described below.

Figure 8. Undrained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Embankment Fill



The selected strength envelope (c = 0.65 tsf and φ = 11º) is plotted with the consolidated undrained (CU) triaxial compression data from tests performed on undisturbed samples of the Embankment Fill as part of historical investigations (Geosyntec 2010a and AECOM 2016b). The data was obtained using maximum deviator stress or 15% axial strain as failure criteria The labels on Figure 8 indicate from which boring the samples were obtained.

In total, data is available from seven CU triaxial compression tests (CU triaxial test). Overall, the data plots along a linear trend. The assigned strength parameters were selected by fitting the CU data per the two-thirds best fit rule (see Appendix E).

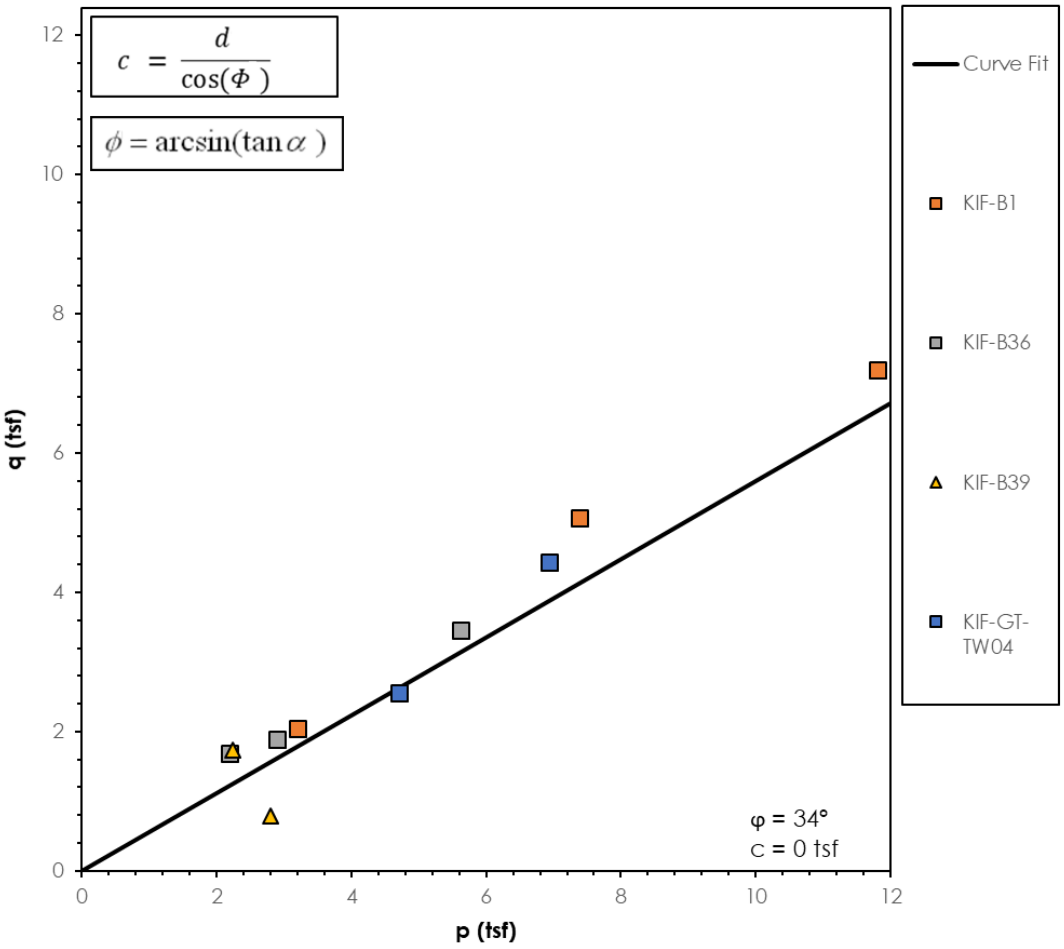
The assigned strength parameters (c = 0.65 tsf and φ = 11º) are different from the values used in the historical Polishing Pond stability analysis. The difference is primarily because an R-envelope (see Appendix E) is employed herein, while a constant value of undrained strength (S_u) was employed in the

historical analysis. The historical Polishing Pond stability analysis used an undrained friction angle of 0 degrees and cohesion of 1500 psf (AECOM 2016b) based on limited data.

4.1.6.2 Fly Ash

Undrained strength (total stress) parameters for the Fly Ash under static, short-term conditions are presented on Figure 9. Determination of these parameters is described below.

Figure 9. Undrained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Fly Ash



The selected strength envelope (c = 0 tsf and ϕ = 34º) is plotted with the CU data from tests performed on undisturbed samples of the Fly Ash material as part of the Exploratory Drilling SAR and the historical investigations (MACTEC 2009 and Geosyntec 2010a). The data were obtained using maximum deviator stress or 15% axial strain as failure criteria. The labels on Figure 9 indicate from which boring the samples were obtained.

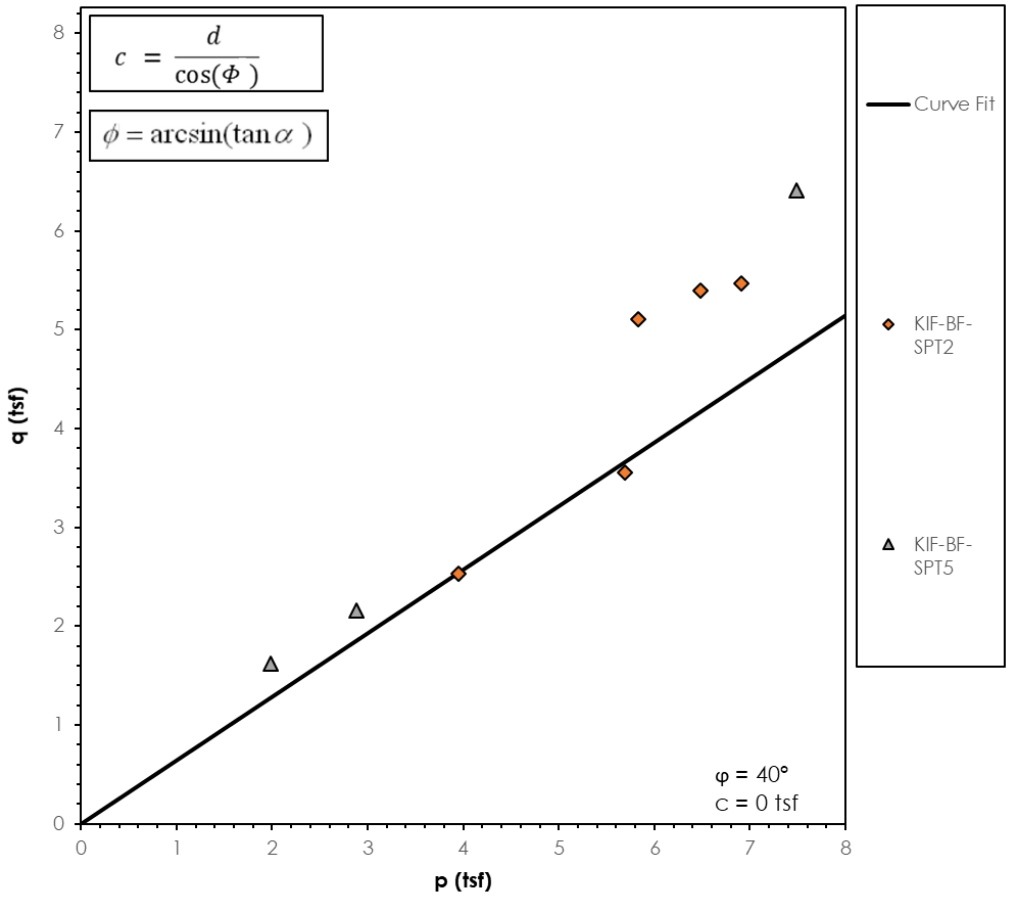
In total, data is available from 10 CU triaxial compression tests. Overall, the data generally plots along a linear trend. The assigned strength parameters were selected by fitting the CU data per the two-thirds best fit rule.

The assigned strength parameters (c = 0 tsf and ϕ = 34º) are higher than what was used in the historical Polishing Pond stability analysis. The historical Polishing Pond stability analysis did not differentiate between the Fly Ash and Bottom Ash materials and modeled them as one material, Ash Fill, with an assigned friction angle of 22 deg. (AECOM 2016b). The strengths assigned in this analysis were determined using additional triaxial data from the Geotechnical Exploration of the KIF Plant (MACTEC 2009) and the Initial Stability Study of the East Dike (Geosyntec 2010a), as well as using a new interpretation of the subsurface conditions separating the Fly Ash and Bottom Ash materials.

4.1.6.3 Bottom Ash

Undrained strength (total stress) parameters for the Bottom Ash under static, short-term conditions are presented on Figure 10. Determination of these parameters is described below.

Figure 10. Undrained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Bottom Ash



The selected strength envelope (c = 0 tsf and φ = 40º) is plotted with the CU data from tests performed on undisturbed samples of the Bottom Ash material as part of historical investigations (AECOM 2016b). The data was obtained using maximum deviator stress or 15% axial strain as failure criteria. The labels on Figure 10 indicate from which boring the samples were obtained.

In total, data is available from eight CU triaxial compression tests. Based on the scatter of the CU data and a relatively small data set, an exact two-thirds fit could not be achieved. The assigned strength parameters were selected by approximating a two-thirds fit, while also considering typical values.

The assigned strength parameters (c = 0 tsf and φ = 40º) are higher than what was used in the historical Polishing Pond stability analysis. The historical Polishing Pond stability analysis did not differentiate between the Fly Ash and Bottom Ash materials and modeled them as one material, Ash Fill, with an assigned friction angle of 22 deg. (AECOM 2016b). The strengths assigned in this analysis were determined by reinterpreting the CU triaxial data from the Polishing Pond stability analysis as well new interpretation of the subsurface conditions separating the Fly Ash and Bottom Ash materials.

4.1.6.4 Cover Material

The Cover Material is assumed to be unsaturated because the material is sufficiently above the capillary fringe and piezometric surface, where no excess pore pressure would develop. Since excess pore pressures are assumed not to develop, the drained strengths assigned in the Static Stability SAR (φ = 19º and c = 0) are assumed. The Cover Material is modeled with a lower drained strength (φ' = 16º and c'=0) in the global stability analysis to account for the geosynthetics interface in the cover system.

4.1.6.5 Filter Materials

The Filter Materials are assumed to be free draining. Independent undrained strength parameters (total stress) were not assigned. The drained strengths (φ = 33º and c = 0) assigned in the Static Stability SAR were assumed.

4.1.6.6 Riprap

The Riprap material is assumed to be free draining. Independent undrained strength parameters (total stress) were not assigned. The drained strengths (φ = 40º, c = 0) assigned in the Static Stability SAR were assumed.

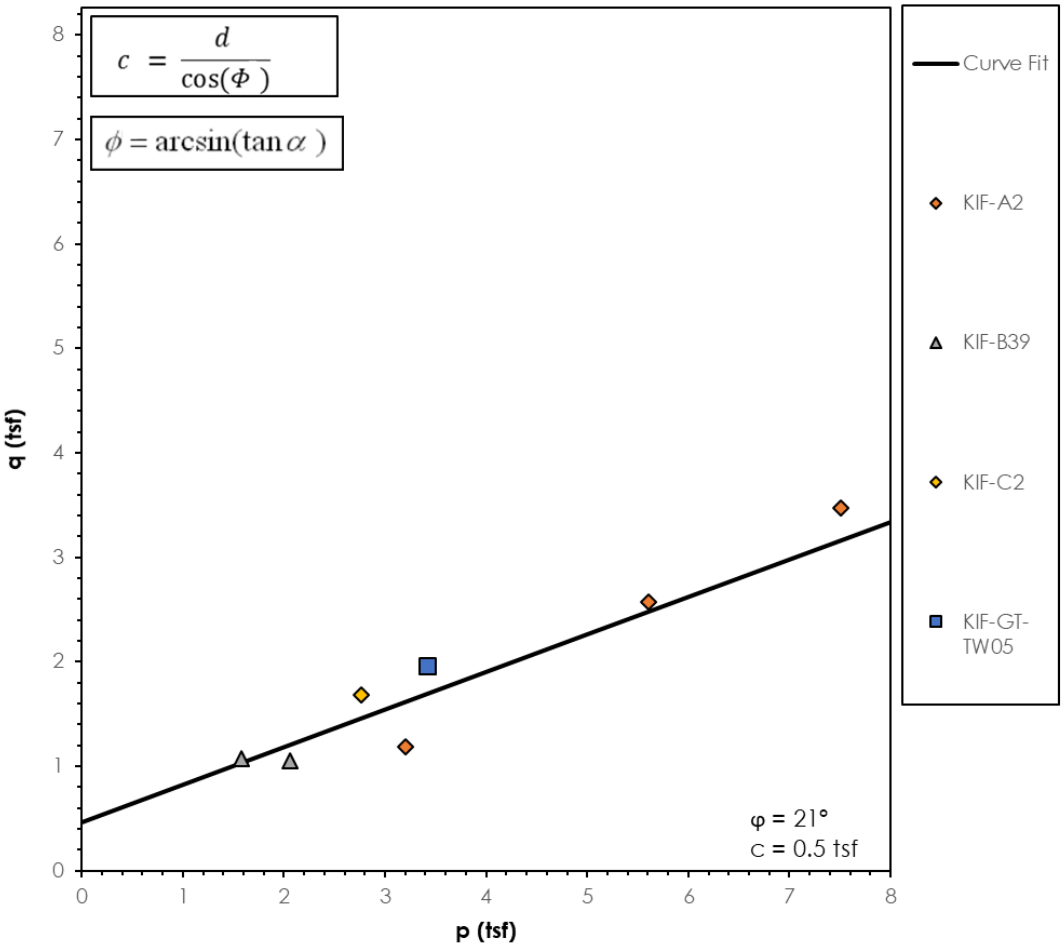
4.1.6.7 Sediment

The determination of the undrained strength parameters (total stress) for the Sediment was not necessary for the seismic stability analyses. Therefore, undrained strength parameters were not assigned for this material.

4.1.6.8 Subunit 1

Undrained strength (total stress) parameters for Subunit 1 under static, short-term conditions are presented on Figure 11. Determination of these parameters is described below.

Figure 11. Undrained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Subunit 1



The selected strength envelope (c = 0.5 tsf and φ = 21º) is plotted with the CU data from tests performed on undisturbed samples of Subunit 1 as part of the Exploratory Drilling SAR and the historical investigations (MACTEC 2009 and Geosyntec 2010a and 2010b). The data was obtained using maximum deviator stress or 15% axial strain as failure criteria. The labels on Figure 11 indicate from which boring the samples were obtained.

In total, data is available from seven isotropically CU triaxial compression tests. Overall, the data generally plots along a linear trend. The assigned strength parameters were selected by fitting the CU data per the two-thirds best fit rule.

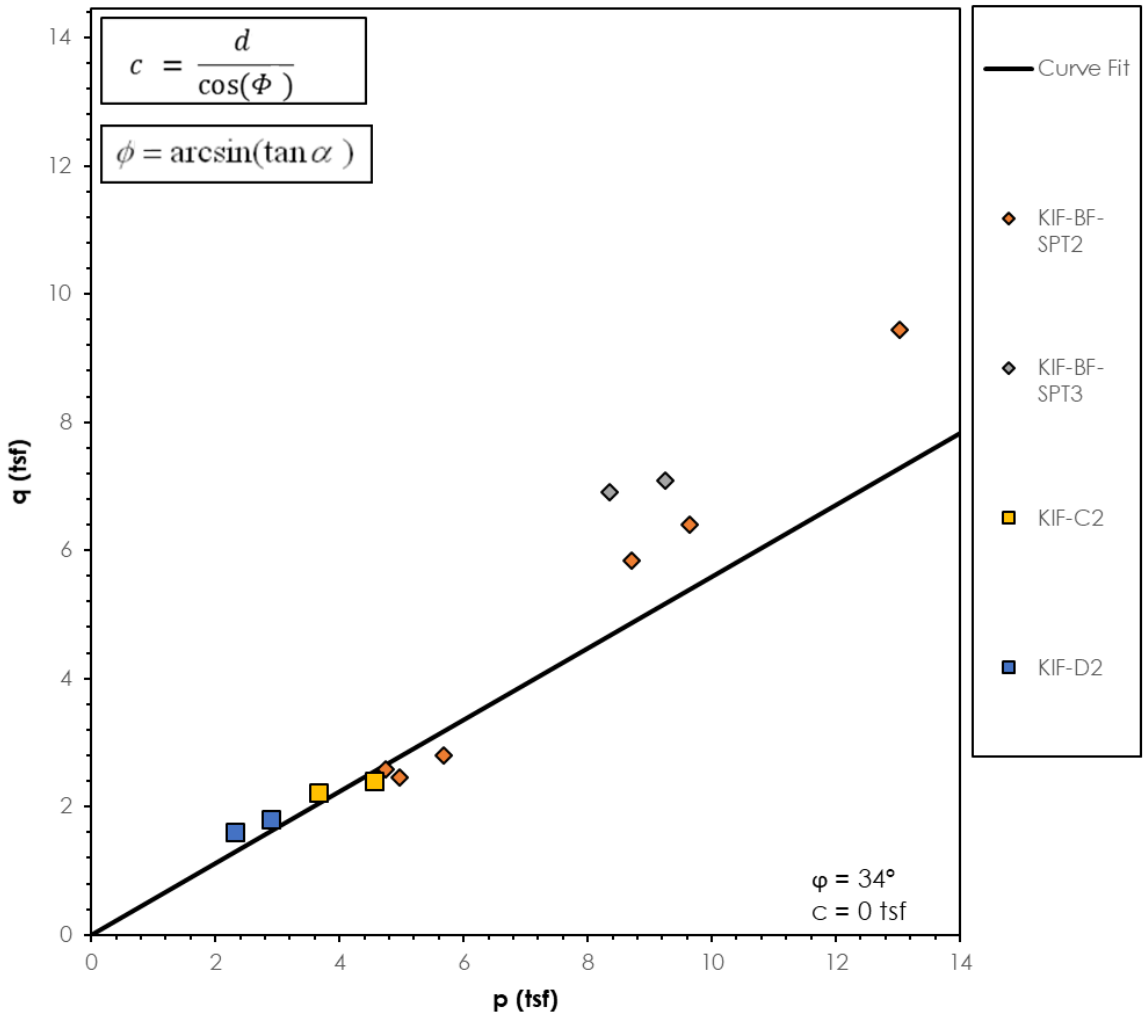
The assigned strength parameters (c = 0.5 tsf and φ = 21º) are higher than what was used in the historical Polishing Pond stability analysis. The historical Polishing Pond stability analysis did not separate the foundation materials into various subunits and modeled them as one material, Silty Sand to Sandy Silt, with an assigned friction angle of 11 degrees and a cohesion of 0.75 tsf (AECOM 2016b)

based on limited data. As provided in the Stilling Pond Updated Seismic Performance (Stantec 2020), an undrained strength of 15 deg. and cohesion of 0.2 tsf was assigned based on laboratory data.

4.1.6.9 Subunit 2

Undrained strength (total stress) parameters for Subunit 2 under static, short-term conditions are presented on Figure 12. Determination of these parameters is described below.

Figure 12. Undrained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Subunit 2



The selected strength envelope (c = 0 tsf and φ = 34º) is plotted with the CU data from tests performed on undisturbed samples of Subunit 2 as part of the historical investigations (AECOM 2016b and Geosyntec 2010b). The data was obtained using maximum deviator stress or 15% axial strain as failure criteria. The labels on Figure 12 indicate from which boring the samples were obtained.

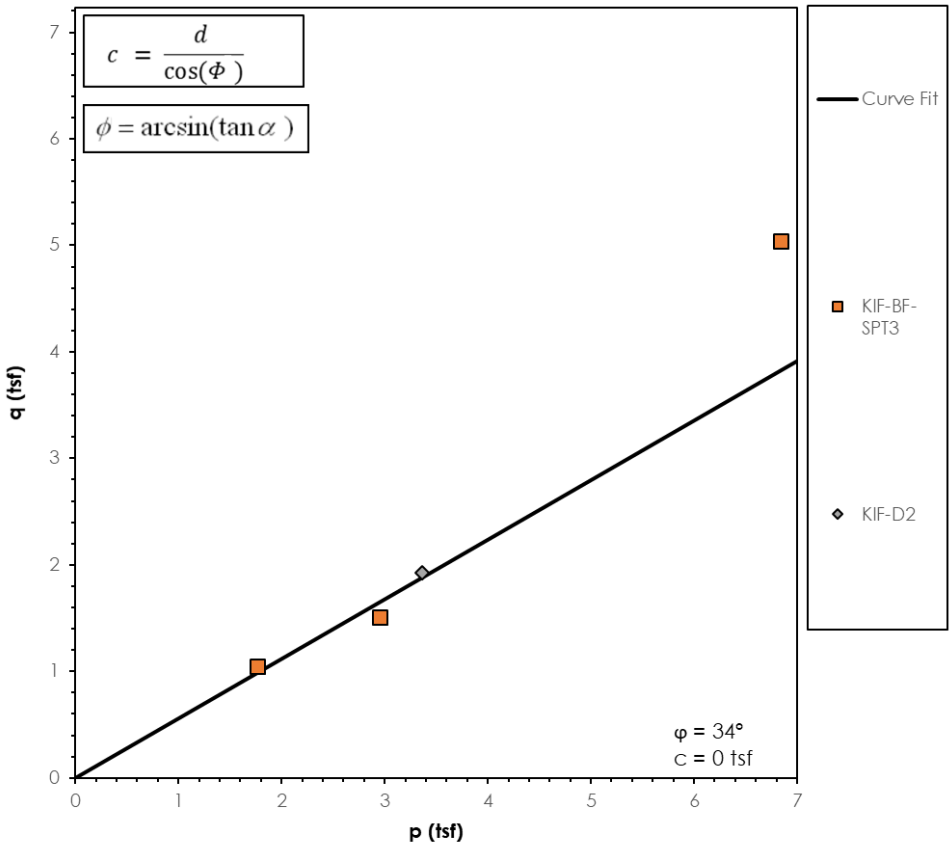
In total, data is available from 12 CU triaxial compression tests. Overall, there is no obvious linear trend in the dataset. The assigned strength parameters were selected by fitting the CU data per the two-thirds best fit rule.

The assigned strength parameters (c = 0 tsf and φ = 34º) are higher than what was used in the historical Polishing Pond stability analysis. The historical Polishing Pond stability analysis did not separate the foundation materials into various subunits and modeled them as one material, Silty Sand to Sandy Silt, with an assigned friction angle of 11 degrees and a cohesion of 0.75 tsf based on limited data (AECOM 2016b). Analysis conducted for the Stilling Pond Updated Seismic Performance (Stantec 2020) considered the material sufficiently permeable such that no significant pore water pressures would develop under static, undrained conditions. That analysis considered the undrained strength to be the same as the drained strength for this material (c = 0 tsf and φ = 26º).

4.1.6.10 Subunit 3

Undrained strength (total stress) parameters for Subunit 3 under static, short-term conditions are presented on Figure 13. Determination of these parameters is described below.

Figure 13. Undrained Failure Stresses and Strength Envelope from Triaxial Compression Tests on Subunit 3



The selected strength envelope (c = 0 tsf and φ = 34º) is plotted with the CU data from tests performed on undisturbed samples of Subunit 3 as part of the historical investigations (AECOM 2016b and Geosyntec 2010b). The data was obtained using maximum deviator stress or 15% axial strain as failure criteria. The labels on Figure 13 indicate from which boring the samples were obtained.

In total, data is available from four CU triaxial compression tests. Overall, the data plots along a linear trend. The assigned strength parameters were selected by fitting the CU data per the two-thirds best fit rule.

The assigned strength parameters (c = 0 tsf and φ = 34º) are higher than what was used in the historical Polishing Pond stability analysis. The historical Polishing Pond stability analysis did not separate the foundation materials into various subunits and modeled them as one material, Silty Sand to Sandy Silt, with an assigned friction angle of 11 degrees and a cohesion of 0.75 tsf (AECOM 2016b) based on limited data. Analysis conducted for the Stilling Pond Updated Seismic Performance (Stantec 2020) considered the material relatively free-draining, such that no significant pore water pressures would develop under static, undrained conditions. That analysis considered the undrained strength to be the same as the drained strength for this material (c = 0 tsf and φ = 30º).

4.1.6.11 Gravel Residuum

The Gravel Residuum material is assumed to be free draining. Independent undrained strength parameters (total stress) were not assigned. The drained strengths assigned in Section 4.1.5.2 (φ = 37º, c = 0) are assumed.

4.1.7 Undrained Strengths for Seismic Conditions

For analyzing seismic stability, the shear strength parameters in Table 8 are used to account for the potential generation of excess pore pressures under dynamic load. These parameters are derived as discussed in Appendix E:

- For saturated soils that do not liquefy, the undrained soil strength parameters are reduced to 80% of the static undrained strength parameters as shown in Table 7
- For very coarse materials, such as rock fill, excess pore pressures will not accumulate, and the drained strength is assumed for the seismic condition
- For unsaturated soils that are sufficiently above the capillary fringe and piezometric surface, excess pore pressures will not accumulate, and the drained strength is assumed for the seismic condition. However, for materials that are only partially above the piezometric surface, it is simpler (and conservative) to model the unsaturated portion using the same seismic undrained strengths applied to the saturated portion.

Consistent with the static undrained stability analyses, the contribution of suction pressures to shearing resistance is effectively neglected by specifying composite drained-undrained strength envelopes (Section 6.1.10). The drained strength parameters, which are applicable at the lower stress range, are not reduced for dynamic pore pressure generation. The shearing resistance at a given normal stress is then

the lesser value of strength computed with the drained or seismic undrained strength parameters (Table 6 and Table 8, respectively).

Table 8. Undrained Shear Strength Parameters for the Analysis of Seismic Loading Conditions for the Subsurface Materials at the KIF Plant

Material Name	ϕ_{EQ} (deg)	c_{EQ} (tsf)
Embankment Fill	9	0.52
Fly Ash[2]	0	0.20
Bottom Ash[3]	34	0
Cover Material[1]	19	0
Filter Materials[3]	33	0
Riprap[3]	40	0
Sediment[2]	0	0.025
Subunit 1	17	0.40
Subunit 2	28	0
Subunit 3[2]	0	0.1875
Subunit 3 (Intake Channel)[2]	0	0.10
Gravel Residuum[3]	37	0

Notes:

ϕ_{EQ} undrained friction angle (seismic conditions) c_{EQ} undrained cohesion (seismic conditions)

1. To account for possible sliding along the geosynthetic interface within the cap system the cover system shear strength was assumed to be (φ = 16º and c = 0) in the global stability analyses.
2. For liquefied materials, the residual strengths were conservatively selected as the seismic strengths rather than the reduced (i.e., 80%), static undrained strengths.
3. Materials where excess pore water pressures assumed to not accumulate. Drained strengths assumed.

4.1.8 Residual Strengths for Liquefied Soils

Liquefaction and cyclic softening potential was assessed for the embankment and foundation materials at the site. The Riprap consists of compacted, angular boulders. The Filter Materials are generally composed of compacted crushed stone or sand. Due to the method of placement of these materials and their free-draining nature, the filter materials are judged to be unliquefiable. The Gravel Residuum is generally composed of gravelly sand and is considered so dense that it is judged to be unliquefiable. Because the Cover Material is unsaturated, it is judged to not be subject to cyclic softening. Therefore, the Riprap, Filter Materials, Gravel Residuum, and Cover Material will not be further discussed with regards to liquefaction or cyclic softening.

Liquefaction and cyclic softening potential was assessed for the Embankment Fill, Fly Ash, Bottom Ash, Subunit 1, Subunit 2, and Subunit 3. First, laboratory and CPT data was used to determine if each material was characteristically clay-like (i.e., potentially susceptible to cyclic softening) or sand-like (potentially susceptible to classic liquefaction). This analysis, summarized in Table 9 and detailed in

Section 7.1.1, found that the Embankment Fill was not susceptible to strength loss due to liquefaction or cyclic softening, regardless of the design earthquake.

Table 9. Summary of Liquefaction Analysis Results for the Subsurface Materials at KIF Plant

Material Name	Clay-like/Sand-like	Liquefaction Predicted?	Cyclic Softening Predicted?
Embankment Fill	Clay-like	No	No
Fly Ash	Sand-like	Yes	No
Bottom Ash	Sand-like	No	No
Subunit 1	Clay-like	No	No
Subunit 2	Sand-like	No	No
Subunit 3	Sand-like	Yes	No

Liquefaction susceptibility was further assessed for the Fly Ash, Bottom Ash, Subunit 1, Subunit 2, and Subunit 3. This analysis determined that the Bottom Ash and Subunit 1 were unliquefiable; that is, the data indicated that the materials were too dense to liquefy or cyclically soften, regardless of the design earthquake.

Next, liquefaction triggering analyses were performed at each SPT boring and CPT sounding location. The results are summarized in Table 9 and the analysis methods are detailed in Appendix F. For the design earthquake, this analysis resulted in predictions of liquefaction in portions of the Fly Ash, Subunit 2, and Subunit 3. However, based on the results of cyclic shear tests conducted on samples of Subunit 2 collected at the Stilling Pond at KIF Plant (Stantec 2020), the soil was determined to not liquefy during the design earthquakes. The cyclic testing results are considered more representative than the empirically based SPT and CPT results for Subunit 2, a borderline sand-like to clay-like material.

The liquefied shear strengths, also referred to as the residual strengths, for the Fly Ash and Subunit 3 were derived for use in the post-earthquake slope stability analysis, using the procedures outlined in Appendix F; the strengths are summarized in Table 10. Based on the Phase 2 Exploratory Drilling data, the zone of Subunit 3 within the intake channel was assigned a slightly lower residual strength, compared to the inboard zone of Subunit 3. To estimate the residual strengths of the Fly Ash and the two zones of Subunit 3, multiple empirical correlations were used and representative values were selected such that an equal number of correlation results lie on each side of the selected value, as shown in Appendix D.

The liquefaction potential of the Sediment was judged qualitatively. As discussed in Section 4.1.1.7, the Sediment is very loose, has very low SPT blowcounts, and has relatively low plasticity. The material was conservatively assumed to liquefy during the design earthquake, and a very low residual strength of 50 psf (0.025 tsf) was assigned. Note that because this deposit is thin and it is located only along the outboard toe of the East Dike, this conservative assumption will have little impact on the results.

The drained strength parameters, which are applicable at the lower stress range (Section 6.1.10), are not reduced for dynamic pore pressure generation. The shearing resistance at a given normal stress is then the lesser value of strength computed with the drained or post-earthquake (residual) strength parameters (Table 6 or Table 10).

Table 10. Residual Strengths for Liquefiable Materials for the Subsurface Materials at KIF Plant

Material Name	ϕ_{LIQ} (deg)	c_{LIQ} (psf)
Fly Ash	0	400
Subunit 3	0	375
Subunit 3 (Intake Channel)	0	200
Sediment	0	50

Notes:

ϕ_{LIQ} undrained friction angle (residual strength) c_{LIQ} undrained cohesion (residual strength)

4.1.9 Shear Strength of Bedrock

The dip of the shale bedrock is to the southeast, which is in the outboard direction relative to the East Dike. This orientation of the bedding planes increases the resistance to sliding within the bedrock. Based on the depth to bedrock, bedding plane orientation, and relative material strengths of the overlying soils, the shale bedrock is modeled as impenetrable in these analyses. See Section 6.1.4 for discussion on how impenetrable materials were considered in the global stability models.

4.1.10 Density and Shear Wave Velocity of Bedrock

The density and stiffness parameters summarized in Table 11 are used in the seismic ground response analyses. As detailed in Appendix F, small-strain stiffness can be measured or characterized in terms of shear wave velocity or small-strain shear modulus. The values for each bedrock zone were determined as described in the subsections below.

Table 11. Small-Strain Shear Stiffness Parameters for the Bedrock Zones beneath KIF Plant

Bedrock Zone	Total Unit Weight γ_t (pcf)		Mass Density ρ_t (slugs/ft^3)	Depth Increment	Shear Wave Velocity V_s (ft/sec)
Shale	Above Elevation 675 ft	140	4.35	*below top of rock:* 0 – 15 ft 15 – 30 ft > 30 ft	 1,220 1,360 1,490
	Below Elevation 675 ft	140	4.35	Depth increments below Elevation 675 ft	$9{,}350 - 10 \times Elev\ (ft)$

For the shale bedrock, published modulus reduction and damping relationships developed by Silva et al. (1996), as presented in Stewart et al. (2008) were used in the ground response analyses. These relationships are available in the *Strata* curve library (Kottke et al. 2013). Selection of appropriate curves were based on the bedrock depth below the ground surface.

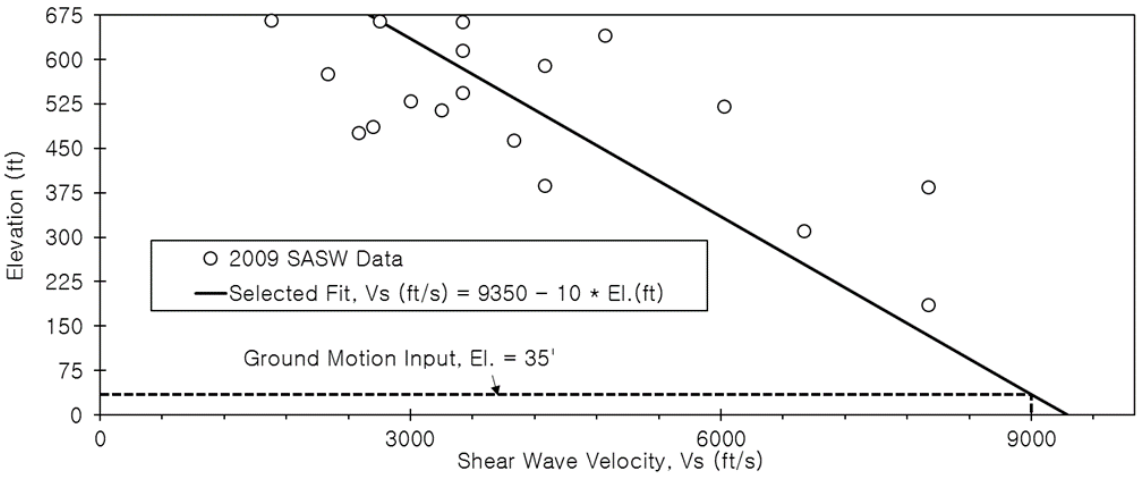
4.1.10.1 Shale Above Elevation 675

The shear wave velocity in the shale bedrock above elevation 675 was developed based on historical Multi-channel Analysis of Surface Waves/Microtremor Array Measurements (MASW/MAM) data collected for the Shear Wave Velocity Testing Project at the Stilling Pond (AECOM 2009). Three intervals of shear wave velocity were developed and assigned to shale above elevation 675, depending on depth below the top of rock (Stantec 2013).

4.1.10.2 Shale Below Elevation 675

The shear wave velocity in the shale bedrock below elevation 675 was estimated using Spectral Analysis of Surface Waves data collected by the University of Texas at Austin (Stantec 2013). The shear wave velocities below elevation 675 were estimated using the equation from the selected fit line, as shown on Figure 14.

Figure 14. Measured Shale Shear Wave Velocity versus Elevation below El. 675, and the Trend Line (Stantec 2013)



4.2 ANALYSIS CROSS SECTIONS

The stability analyses are performed for the specific cross sections listed in Table 12 and shown on Figure 15. Per the Stability SAP, the selected locations represent critical cross sections based on reviews of previous stability analysis results, subsurface stratigraphy, material properties, and structure geometry. For selection of analysis section(s) for post-earthquake stability, the location of potentially liquefiable materials is also considered. If the previously used cross sections were not considered representative for the new analyses, sections were updated or new cross sections were developed using available site-specific data (including data from the Exploratory Drilling SAR). The following subsections present the specific basis for the selection of each section.

Table 12. Analyzed Cross Sections at KIF Plant

CCR Unit	Cross Section	Notes
Sluice Trench and Ballfield East of Sluice Trench	A-A'	Southwest portion of the East Dike near the intake channel at KIF Plant
Sluice Trench and Ballfield East of Sluice Trench	Polishing Pond	Central portion of the East Dike, including the Polishing Pond but excluding the Engineered Wetlands
Sluice Trench and Ballfield East of Sluice Trench	Typical (veneer only)	Representative section for veneer stability analysis; steep portion of the Polishing Pond section.

The previous global slope stability analysis results (Geosyntec 2010a, 2010b, and 2012, AECOM 2016a) for the Sluice Trench and Ballfield East of the Sluice Trench were reviewed to identify the critical cross section(s) for the pseudostatic and post-earthquake loading conditions. Geosyntec (2010a, 2010b, and 2012) considered four slope stability cross sections (Sections A, B, C, D) at the Sluice Trench and Ballfield East of the Sluice Trench. The analyses included static, long-term global cases for the four sections and also seismic (pseudostatic) cases for Sections C and D. Sections C and D included the buttressing effect of the Engineered Wetlands and were judged to be non-critical. Because seismic analyses were not performed for Sections A and B, the static stability results were used to identify the critical cross sections for the unit. The lowest factors of safety for long-term global stability (for the existing condition at that time) were reported at Section A (FS=1.7) and Section B (FS=1.6). During the planning and design of the Polishing Pond, AECOM (2016a) analyzed the "Polishing Pond" cross section, which is located near Geosyntec's Section B. The analysis included pseudostatic and post-earthquake load cases. For the pseudostatic case, the AECOM (2016a) analysis considered a slip surface intercepting the Polishing Pond pool (FS=1.6), so the results are not directly comparable to the slip surface criteria used herein. The post-earthquake case considered a slip surface through the East Dike and intercepting the CCR (FS=1.0). Since the previous analyses, the Polishing Pond has been constructed and the Sluice Trench and Ballfield East of Sluice Trench has been regraded (including fill placed between the Polishing Pond and the East Dike) and capped with geosynthetics and cover soil (AECOM 2019). The outboard slope of the East Dike was also modified for seepage mitigation purposes (AECOM 2017). Based on the historical analysis results and the current unit geometry, Section A-A' and the "Polishing Pond" were selected as the critical cross sections to represent the seismic global stability for existing conditions at the Sluice Trench and Ballfield East of Sluice Trench.

Figure 15. Cross section locations

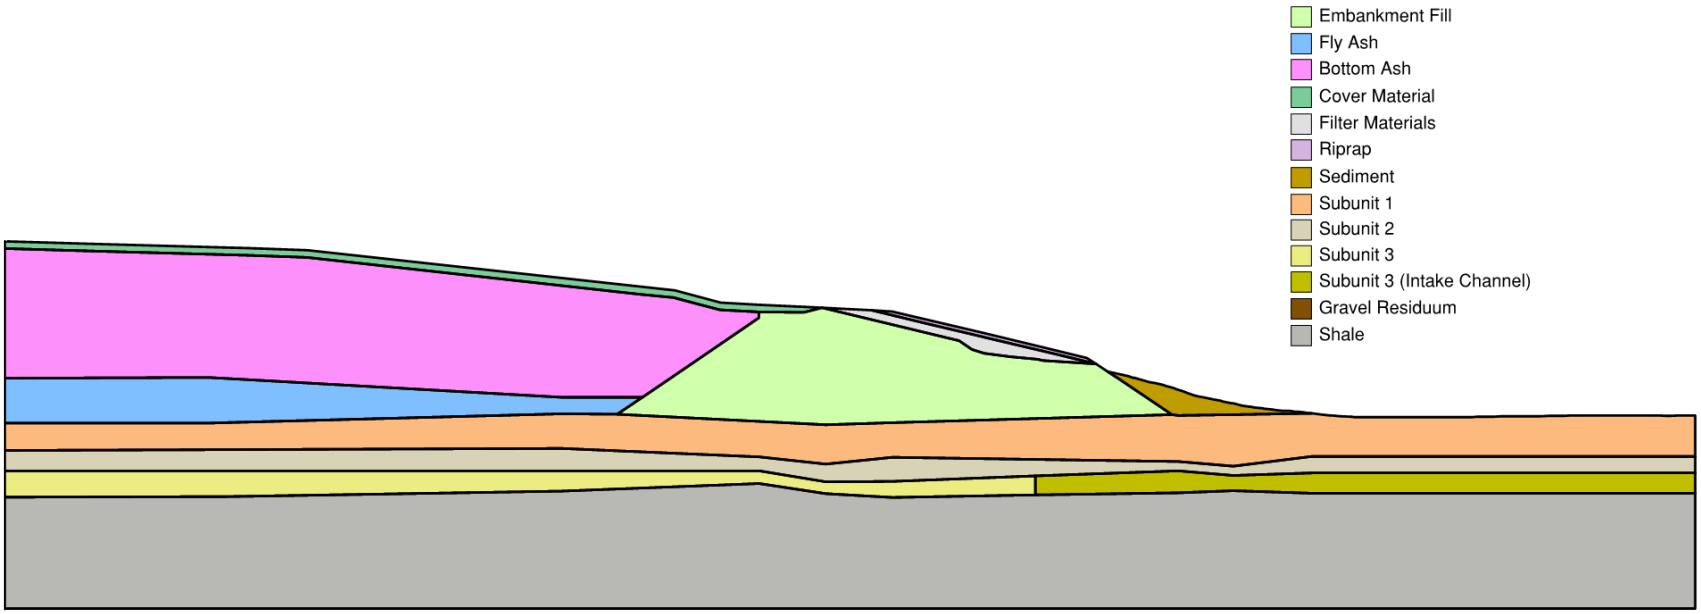
4.2.1 Cross Section A-A': Basis for Selection

Cross section A-A' was selected to represent the typical slope geometry of the portion of the East Dike near the intake channel. This section was previously analyzed by Geosyntec (2010a and 2012). Since the previous analyses, the Sluice Trench and Ballfield East of Sluice Trench has been regraded and capped with geosynthetics and cover soil (AECOM 2019). The outboard slope of the East Dike was also modified for seepage mitigation purposes (AECOM 2017).

The geometry of the groundline was developed by combining the plant-wide LiDAR survey, completed in 2017, the top of ground surveys (i.e., as-built surveys) completed as part of the seepage mitigation construction and closure construction at the East Dike, and a bathymetric survey completed in 2020 as part of the Phase 2 Exploratory Drilling. The original design drawings depict the geometry and extents of the material used in the construction of the East Dike, which is comprised of lean clay fill, with some shale fragments. The outboard face of the dike has a reverse graded filter, which consists of Filter Materials between the Embankment Fill and Riprap. The Cover Material represents the cap system installed over

the Fly Ash and Bottom Ash materials on the inboard side of the East Dike. The section is underlain by alluvial foundation soil, beginning with an alluvial clay (Subunit 1) transitioning to silty sand (Subunits 2 and 3). The foundation soil in the intake channel is generally overlain by a thin veneer of Sediment. Figure 16 shows the analysis section with the various materials color-coded for ease of review.

Figure 16. Materials in Stability Analysis Section A-A

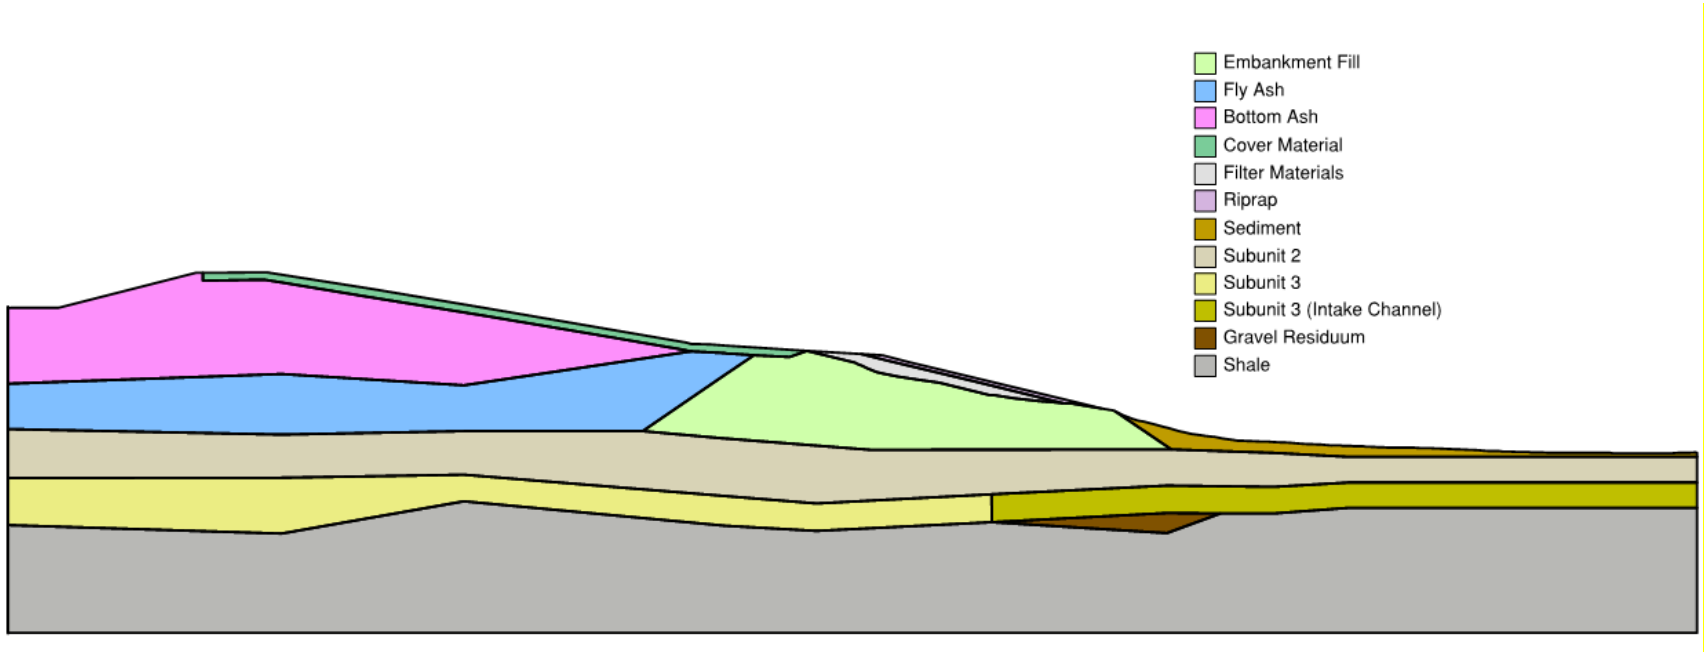


4.2.2 Cross Section “Polishing Pond”: Basis for Selection

Cross section “Polishing Pond” was selected to represent the typical section of the East Dike that includes the Polishing Pond but excludes the buttressing effect of the Engineered Wetlands. This section was previously analyzed by AECOM (2016a) during the planning and design of the Polishing Pond; however, since the previous analyses, the Sluice Trench and Ballfield East of Sluice Trench has been regraded (including fill placed between the Polishing Pond and the East Dike) and capped with geosynthetics and cover soil (AECOM 2019). The outboard slope of the East Dike was also modified for seepage mitigation purposes (AECOM 2017).

Similar to Section A-A’, the geometry of the groundline was developed by combining the plant-wide LiDAR survey, completed in 2017, the top of ground surveys (i.e., as-built surveys) completed as part of the seepage mitigation construction and closure construction at the East Dike, and a bathymetric survey completed in 2020 as part of the Phase 2 Exploratory Drilling. Additionally, the record drawings for the newly constructed Polishing Pond were used to update the slope and pond geometry. The outboard face of the dike also has a reverse-graded filter, which consists of Filter Materials placed on the outboard face of the Embankment Fill and covered with Riprap. The Polishing Pond was constructed overtop of the Fly Ash and Bottom Ash, which is retained by the East Dike. The section is underlain by alluvial foundation soil, beginning with alluvial sandy silt (Subunit 2) and transitioning to a silty sand (Subunit 3) above bedrock. In one small portion of the intake channel at this section, Gravel Residuum was encountered between Subunit 3 and the bedrock. As noted in Section 4.1.1.7, Subunit 1 is generally absent in this vicinity and was not modeled. The foundation soils modeled along the outboard toe of the East Dike are overlain by a thin layer of sediment, similar to Section A-A’. Figure 17 shows the analysis section with the various materials color-coded for ease of review.

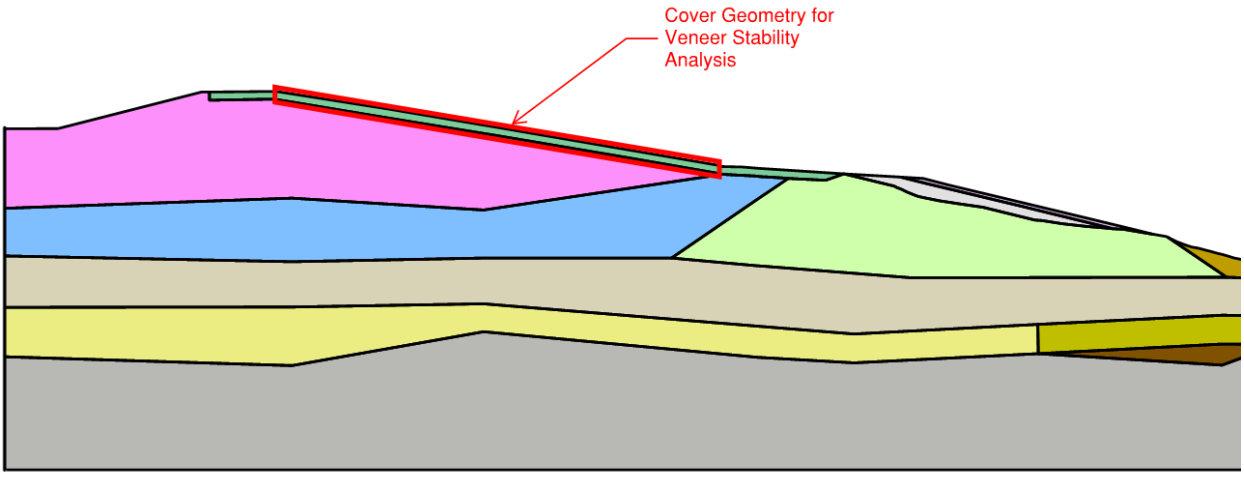
Figure 17. Materials in Stability Analysis Section "Polishing Pond"



4.2.3 Typical Section for Veneer Stability: Basis for Selection

The veneer stability was evaluated at the steepest section within the unit (Figure 18), along the Polishing Pond section, with the 2.0 ft of soil above the geosynthetic components, where the mid-slope angle is 10 degrees and the mid-slope height is 11.2 ft above the access road.

Figure 18. Selected geometry for Veneer Stability analyses



5.0 LOADING CONDITIONS AND ACCEPTANCE CRITERIA

5.1 LOAD CASES, PHASED ASSESSMENT, AND ACCEPTANCE CRITERIA

The load cases, phased assessment, and acceptance criteria presented here were approved in the EIP (Stantec 2018b). The Stability SAP (2018a) contains a detailed explanation of the basis for the load cases and acceptance criteria.

The load cases to be evaluated in the stability analyses are based on conventional practice and appropriate industry standards for landfills and surface impoundments, as applicable.

- Seismic, pseudostatic global stability
- Seismic, pseudostatic veneer stability
- Seismic, post-earthquake global stability (includes a preceding liquefaction triggering assessment).

The stability analyses defined in the Stability SAP are performed using a phased assessment process. Initial phases employ available site information, simplified analysis methods, and more conservative acceptance criteria. If acceptable performance is demonstrated, the analyses for the particular load case(s) are then complete. If not, the next phase may include collection of additional site information and/or more advanced analysis methods. Less conservative acceptance criteria may be utilized, commensurate with the improved site characterization. The process may continue through multiple phases, as outlined in the Stability SAP. The use of a phased approach is consistent with industry standard engineering practices.

The load cases and acceptance criteria presented herein (Table 13) apply specifically for the TDEC Order. The same CCR units may also be subject to other requirements (which may be more or less stringent) for compliance with other regulations such as state permitting, CCR Rule, etc. This Stability SAR documents Phase 2 TDEC Order stability assessments as noted in Table 1. The process for Phase 1 and 2 assessments are as follows:

Phase 1 Assessment (Seismic Load Cases)

- Use available geotechnical data SPT, CPT, laboratory testing, etc.
    - Where geotechnical data is insufficient, collect supplemental data.
- For seismic load cases, use site-specific design earthquake loading
    - If not already available, TVA will perform site-specific seismic hazards assessment (Section 5.3).

- Complete liquefaction triggering assessment based on SPT and CPT data
- Compute pseudostatic factor of safety (global, FS_{pseudo} and veneer, $FS_{pseudo\text{-}veneer}$ slope stability)
    - Using Newmark displacement analyses, compute displacements for range of yield accelerations
    - Select pseudostatic coefficient equal to yield acceleration that gives displacement of three feet in the Newmark analysis
    - Assign strengths considering results of liquefaction assessment
    - Compute pseudostatic FS_{pseudo} and $FS_{pseudo\text{-}veneer}$.
- Compute static, post-earthquake factor of safety (global slope stability)
    - Assign pseudostatic coefficient equal to zero (static case)
    - Assign strengths considering results of liquefaction assessment
    - Compute post-earthquake $FS_{post\text{-}EQ}$.
- Performance is acceptable if the following criteria are met
    - $FS_{pseudo} \geq 1.0$
    - $FS_{pseudo\text{-}veneer} \geq 1.0$
    - $FS_{post\text{-}EQ} \geq 1.1$.
- If any load cases do not meet criteria, go to Phase 2.

Phase 2 Assessment (Seismic Load Cases)

- Perform additional site explorations in targeted areas
    - Critical areas to be identified by parametric analyses
    - SPT using mud rotary drilling (or other suitable drilling method)
    - Seismic CPT soundings (companion to SPT locations)
    - Lab testing tailored to analysis needs (including triaxial and/or direct shear strength testing, as applicable).
- Complete liquefaction triggering assessment
    - Update Phase 1 analyses with new site data.
- Compute pseudostatic factor of safety (FS_{pseudo} and $FS_{pseudo\text{-}veneer}$)

    - Update Phase 1 analyses with new site data.

- Compute post-earthquake factor of safety ($FS_{post\text{-}EQ}$)
    - Update Phase 1 analyses with new site data.
- Performance is acceptable if the following criteria are met
    - $FS_{pseudo} \geq 1.0$
    - $FS_{pseudo\text{-}veneer} \geq 1.0$
    - $FS_{post\text{-}EQ} \geq 1.0$ (lower criteria based on improved site characterization).
- If any load cases do not meet criteria, go to Phase 3 (refer to Stability SAP).

Refer to the Stability SAP for discussion of other phases of stability assessment.

Table 13. Summary of Load Cases and Acceptance Criteria

Load Case	Pool Levels	Incipient Motion	Analysis	Soil Strengths	Pore Pressures	Acceptance Criteria
Pseudostatic, Global and Veneer	Impoundment (where applicable): Normal Operating Pool Adjacent Reservoir: Winter Pool	Inboard (Impoundments Only) and Outboard	Undrained Seismic	Undrained Seismic	Seepage for Modeled Pool Levels and/or Piezometer Data	FS ≥ 1.0 (Correlated to tolerable displacement of 3 feet[1])
Post-Earthquake, Global	Impoundment (where applicable): Normal Operating Pool Adjacent Reservoir: Winter Pool	Inboard (Impoundments Only) and Outboard	Undrained Static	Undrained Seismic; Residual Strengths in Liquefied Materials	Seepage for Modeled Pool Levels and/or Piezometer Data	FS ≥ 1.0 (Phase 2)

Notes:

1. Tolerable displacement subject to adjustment based on site-specific features and consequences of specific failure modes.

5.2 POOL LEVELS AND PORE WATER PRESSURES

Table 14 presents the pool levels and the basis of the phreatic surfaces used to predict pore pressures in the slope stability analyses.

For seismic load cases, the pool within an impoundment (where applicable) is the normal operating pool. The pool in the adjacent body of water (e.g., river or reservoir) is the normal operating pool (Summer or Winter Pool, whichever is more conservative) for the reservoir.

The slope stability analyses require pore water pressures for computing effective consolidation stresses, as defined for the load conditions. Pore water pressures were estimated by assigning a piezometric line to the cross section based, in part, on available site-specific piezometer data.

Consideration of both estimated pore water pressures and adjacent reservoir pool levels (where applicable) will generally encompass the phreatic conditions that will be experienced by the unit.

Table 14. Pool Levels and Phreatic Surfaces at KIF Plant

CCR Unit	Pool Levels		Basis of Phreatic Surface
	Impoundment	Adjacent Water Body	
Sluice Trench and Ballfield East of Sluice Trench	N/A	Emory River/Intake Channel	Nearby temporary well and piezometer data. Construction records for seepage mitigation system along East Dike.

The Emory River (including the Intake Channel for the KIF Plant) is adjacent to the East Dike at each cross section. The Emory River joins the Tennessee River just downstream of the site, both of which are then impounded by Watts Bar Dam approximately 38 miles downstream from the KIF Plant. The headwater of Watts Bar Dam varies seasonally per a prescribed operating guide, which includes target elevations for Winter and Summer Pools. The annual operating guide for Watts Bar Dam targets the Winter Pool, which is approximately five feet lower than the targeted Summer Pool, from December 1 to April 1 (TVA 2020). This seasonal change is observed in the Emory River water levels at the KIF Plant, as recorded by an onsite river gauge. The Winter Pool was modeled in the stability analyses because the lower pool (compared to the Summer Pool) provides less resisting force along the outboard slope of the East Dike and thus is more conservative for slope stability analysis. For this analysis, the elevation of the Winter Pool was defined as the median elevation for the two most recent winters of daily readings during the periods of December 1, 2018 to April 1, 2019 and December 1, 2019 to April 1, 2020. This pool elevation was calculated to be 737.4 ft.

The phreatic surfaces for both sections were developed using the calculated onsite Winter Pool and piezometric data collected from temporary wells and piezometers installed at the Sluice Trench and Ballfield East of Sluice Trench. The piezometric data were obtained from TVA's geotechnical instrumentation database. Median values of available piezometric data from the past two years were used. For most instruments, the available data consisted of periodic readings from May to December

2019 and one reading from April 2020. The available data for vibrating wire piezometers KIF-B09A, KIF-B09B, KIF-B13A, and KIF-B13B, which were installed during the Phase 2 Exploratory Drilling, consisted of automated readings from April to June 2021. The instruments used to create the phreatic surface for Section A-A' include temporary well KIF-TW04 and piezometers PZ-A1, PZ-A2, KIF-B09A, and KIF-B09B (Geosyntec 2010a). The instruments used to create the phreatic surface for the Polishing Pond Section include the temporary wells KIF-TW04 and KIF-TW05, and piezometers PZ-B1, PZ-B2, PZ-B3, KIF-B13A, and KIF-B13B (Geosyntec 2010a). The instruments are located between the interior of the adjacent Interim Ash Staging Area and the crest of the East Dike. Generally, the instruments used for the phreatic surface at the Polishing Pond section were southwest of the section. The instruments used for the phreatic surface at Section A-A' generally aligned with the cross section. The piezometric surface at the outboard face of the East Dike was controlled by the invert elevation of the seepage collection pipe at each section, as defined in construction documentation from the KIF East Dike Seepage Mitigation project (AECOM 2017).

It should be noted that the Polishing Pond (Figure 1), located partially within the boundaries of the Sluice Trench and Ballfield East of Sluice Trench CCR unit, is lined with geomembrane. Thus, the water in this pond is hydraulically isolated from the subsurface and does not influence the underlying phreatic surface. However, the weight of the water within the pond was included as a surcharge load in the Polishing Pond analysis section. The surcharge load was modeled for a pond elevation of 769.2 ft, which is the designed normal pool (AECOM 2016b).

5.3 SEISMIC LOADING

The design earthquake is an event with a two percent probability of exceedance in 50 years (i.e., return period of 2,475 years). This return period is similar to that of an event with a 10% probability of exceedance in 250 years (return period of 2,373 years).

Seismicity at the KIF Plant can primarily be attributed to the New Madrid seismic zone and smaller, less concentrated crustal faults relatively closer to the plant. The New Madrid seismic zone, located along the borders of Tennessee, Kentucky, Arkansas, and Missouri, is capable of producing large magnitude earthquakes, and relatively long durations of ground shaking across the area. While other seismic sources, that may represent significant seismic risks at the KIF Plant, are associated with maximum earthquake magnitudes less than the New Madrid seismic zone, larger accelerations may occur due to their closer proximity to the site (Stantec 2017). The two earthquake scenarios that were considered in the evaluation of the pseudostatic global stability, post-earthquake global stability, and seismic veneer stability of the Sluice Trench and Ballfield East of Sluice Trench at the KIF Plant are:

- The near-field event represents a local, moment magnitude (M_w) = 6.0 earthquake, originating in the East Tennessee Seismic Source Zone. This earthquake scenario produces higher accelerations with dominant frequencies in the range of 10 Hertz (Hz). The peak ground acceleration (hard rock) for this event is 0.106 times the acceleration due to gravity (g).
- The other design earthquake is a far-field, M_w = 7.6, New Madrid event originating in western Tennessee. This event has a larger magnitude but is much farther from the site. The resulting

accelerations are lower, and also in the lower frequency range of about one Hz. The peak ground acceleration (hard rock) for this event is 0.033 g.

This seismic hazard model is the same as that considered in the design of the adjacent dredge cell closure (i.e., KRP Ash Landfill) and adjacent Stilling Pond closure at the KIF Plant.

For the stability analyses, multiple acceleration time histories were used to represent expected bedrock motions under the unit during the design earthquakes. Seven-time histories were developed by Stantec (2019) for the one Hz scenario. Seven-time histories were developed by Stantec (2019) and six-time histories were developed by AMEC Geomatrix (2009) for the 10 Hz scenario. These motions are the same as those considered in the design of the adjacent Stilling Pond closure. Ground response analyses were used to predict the resulting seismic loads in the soil column and unit. Peak accelerations at the ground surface were computed for use in the liquefaction triggering analyses. Acceleration time histories along potential failure surfaces were also estimated, as needed for the seismic deformation analyses. Refer to Appendix D for details of the ground response analyses.

6.0 METHODOLOGY

6.1 GENERAL

6.1.1 Software

Slope stability is evaluated using conventional, limit equilibrium methods as implemented in the GeoStudio SLOPE/W 2016 software (GEO-SLOPE 2015). Available from GEO-SLOPE International, Ltd., of Calgary, Alberta, Canada (www.geo-slope.com), SLOPE/W is a special-purpose computer code designed to compute the stability of earth slopes using two-dimensional, limit equilibrium, method of slices analyses. SLOPE/W 2016, version 8.16, is used for the analyses described herein. With SLOPE/W, the distribution of pore water pressures within the earth mass may be mapped directly from the results of a SEEP/W analysis.

6.1.2 Assumed System(s) of Slice Forces

Limit equilibrium methods for evaluating slope stability consider the static equilibrium of a soil mass above a potential failure surface. In conventional, two-dimensional methods of analysis, the slide mass above an assumed failure surface is split into vertical slices. Stresses are evaluated along the sides and base of each slice. The factor of safety against a slope failure (FS_{slope}) is defined as:

$$FS_{slope} = \frac{shear\ strength\ of\ soil}{shear\ stress\ required\ for\ equilibrium} \qquad \textbf{Equation 1}$$

where the strengths and stresses are computed along a defined failure surface, on the base of the vertical slices. The shearing resistance at locations along the potential slip surface is computed, with appropriate Mohr-Coulomb strength parameters, as a function of the total or effective normal stress.

Spencer's solution procedure (Spencer 1967), which satisfies the conditions of equilibrium for each slice, is used in this study. Key assumptions and features of Spencer's method include (United States Army Corps Engineers 2003; Duncan and Wright 2005):

- Interslice forces are assumed to have the same inclination angle with respect to the horizontal. The inclination is computed as part of the solution.
- The normal force on the base of each slice is assumed to act at the center of the base
- A trial and error solution is required, to solve for equilibrium
- Force and moment equilibrium are satisfied for each slice, and the overall slide mass
- Circular and noncircular potential failure surfaces can be evaluated
- The procedure computes FS_{slope} for an assumed failure surface. A search must be made to find the critical slip surface corresponding to the lowest FS_{slope}.

6.1.3 Optimization Scheme to Define Critical Rupture Surface

Once a critical slip surface is identified by the automated search routine, the "optimization" feature in SLOPE/W is used to consider the possible effects of localized changes in the slip surface. The code divides the critical slip circle into linear segments, then moves the end points while searching for a surface that yields a lower FS_{slope}. The optimization routine will sometimes produce a slip surface with reverse curves, or one that is not otherwise kinematically logical. If the inferred, failure mechanism is not a realistic representation of slope movements, the "optimized" result is discarded.

A variety of these methods is used in searching for the critical slip surface. The details of the employed strategy are relatively unimportant, however, as different approaches usually lead to similar answers. The final failure surface, representing the critical slip surface associated with FS_{slope}, is selected by the engineer based on the analytical results, the automated search outcomes, and knowledge of the geotechnical conditions.

6.1.4 Shapes of Rupture Surfaces Considered

SLOPE/W includes several options and trial routines to facilitate the search for the critical failure surface (GEO-SLOPE 2015). In the "grid and radius" search method, a region (divided into a grid) for the circle centers and a range of possible radii are specified for the trial slip circles. The code then automatically evaluates a large number of trial circles within those parameters, searching for one circle having the lowest FS_{slope}. In the "entry and exit" method, the search considers potential slip circles that intersect the ground surface within specified ranges. Where a potential failure circle intersects a much stronger, "impenetrable" layer (such as rock), SLOPE/W automatically evaluates composite slip surface (circles with straight-line portions along the interface). Non-circular slip surfaces are considered using the "block method".

Slip surfaces are evaluated for two conditions in the analyses: failure surfaces that intercept the contained CCR and shallow (D_{min} = 10 ft) failure surfaces. See additional discussion in Section 6.1.5.

6.1.5 Consideration of Shallow Slope Instabilities

When an earth slope is comprised of a cohesionless soil, an infinite slope mechanism will have the least resistance to sliding. An infinite slope failure will result in shallow raveling of the embankment slope. Localized, shallow slips of this type can be repaired to prevent progression to a deeper sliding mechanism, such that infinite slope failures are usually considered as a potential maintenance issue. Moreover, capillary stresses (which are neglected in the analysis) in the near surface soil will create an apparent cohesion that resists shallow sliding.

In a stability analysis where the surficial soil is modeled with a strength envelope having zero cohesion (c = 0), the lowest factor of safety will be computed for shallow sliding parallel to the slope face. The slope stability analyses presented here are focused on the potential for slope failures of significant mass, which could directly impact the safety of the CCR unit. The search for a critical slip surface in the stability analyses is thus restricted, to consider only potential surfaces where the depth (measured at the base of

at least one slice) is more than 10 ft vertically below the ground surface. Shallower slip surfaces at depths less than 10 ft, representing infinite slope failures, are ignored in the analysis.

The minimum specified depth may be increased or decreased as needed to study failure mechanisms for a given slope geometry. Consideration of sliding depths less than 10 ft may be warranted on relatively short structures. Other criteria are appropriate where shallow sliding could initiate a progressive failure that would impact a significant portion of the CCR unit or critical project components. Any history of shallow slides at the CCR unit would be relevant.

In cases where shallow surface sliding is found to give the lowest safety factor, additional analyses are completed to evaluate failure surfaces that would intercept the contained CCR within the unit. The search parameters are set to find a critical slip surface that intercepts CCR within the unit.

This “CCR intercept” stability analysis will indicate a different factor of safety, for a potential failure mode that would more clearly correspond to an unacceptable CCR release condition. In reporting the stability results, the CCR intercept failures are thus given greater emphasis than the failures that do not intercept CCR.

6.1.6 Exclusion of Retrogressive Slope Failure Mechanisms

A retrogressive slope failure (sometimes called a progressive slope failure) develops as a sequence of soil movements, where an initial slide mass triggers additional movement farther up the slope. If not remediated, a retrogressive failure on a CCR unit can eventually progress to the contained CCR and lead to an uncontrolled release.

Retrogressive slope failures are not evaluated herein. If acceptance criteria are met for the load cases under consideration, a retrogressive slope failure will be unlikely. Furthermore, retrogressive failures develop over a period of time and should be identified with sufficient time for intervention to remediate the failure before the contained CCR is impacted.

6.1.7 Tension Cracks

When the soils at the head of a slip surface are assigned cohesive strength (c > 0) in a slope stability analysis, tensile stresses are often computed along the base of the slices in that area. In the field, tensile stress results in the opening of a tension crack, reducing the lateral stresses to zero. Because tension results in a stabilizing force at the head of the slide mass, it is unconservative to have tensile stresses between the slices in a slope stability analysis. This problem is discussed by Duncan and Wright (2005).

When tensile stresses are reported in the stability calculation, a vertical tension crack is introduced into the analysis at the ground surface. The crack depth is increased until tensile stresses (negative normal stresses on the base of a slice) are no longer indicated. The depth of the tension crack (d_{crack}) should not exceed this theoretical maximum value:

$$(d_{crack})_{max} = \frac{2\,c_d}{\gamma_m \tan(45 - 0.5\phi_d)}$$ **Equation 2**

Here, γ_m is the moist unit weight, and c_d and ϕ_d are the developed shear strength parameters ($c_d = c / FS_{slope}$, $\tan\phi_d = \tan\phi / FS_{slope}$), for the upper soil layer at the head of the slip surface.

For earthquake load cases, tension cracks are assumed to be dry. For other load cases, an incipient failure may coincide with rain and surface runoff, which would fill a tension crack with water and create an additional lateral force on the slide mass. Tension cracks are thus assumed to be full of water for these load cases.

6.1.8 Drained versus Undrained Analyses

Conventional, geotechnical stability is evaluated for only two bounding conditions:

- Drained conditions, where the pore pressures are assumed to be unchanged, shear strengths are computed based on the effective stress at failure, and effective stress stability analyses are used
- Undrained conditions, where the final pore pressures (including pore pressures induced by shearing) are unknown, shear strengths are constant or computed based on the effective consolidation stress, and total stress analyses are used.

The inherent assumptions for each condition are summarized in Table 15. The type of analysis to be used for each load case is defined in Section 5.1.

When setting up the slope stability analysis, each material zone is considered individually to determine which strength parameters (drained or undrained) should be assigned for a particular load case. Within an undrained, total stress stability analysis, it may be appropriate to treat some permeable material zones as fully drained (that is, assume no excess pore pressure at failure and assign effective stress strength parameters), while undrained strength parameters are specified in other zones.

The decision to treat a particular material zone as drained or undrained is based on how rapidly the loading condition develops with respect to how quickly pore pressures induced by the loading can dissipate. In most cases, clean, coarse rockfill will be fully drained under the considered loading conditions, even during seismic loading. Most other soils, including sands, will behave undrained during seismic loading. In marginal cases, the time factor (T) can be estimated to judge when a particular soil zone is drained or undrained in a particular load case (see Appendix E).

For either drained or undrained stability analyses, pore pressures are specified for each material zone consistent with how the strength parameters model the shearing resistance in that soil. The input pore pressures are used to compute the effective consolidation stresses along the trial failure surfaces. When “drained” strengths (c’, ϕ’) or “consolidated undrained” (c, ϕ) strengths are used, the shearing resistance is computed from the consolidation stresses normal to the failure surface. When undrained strengths are characterized using c/p (S_u/σ'_{vo}) ratios, the shearing resistance (S_u) is computed based on the vertical effective stress to which the soil has been consolidated at points along the slip surface. Technically, pore pressures are not needed where “unconsolidated undrained” (S_u, $\phi = 0$) strengths are specified. Because the assigned strength is constant in this case, pore pressures input for $\phi = 0$ soils will have no impact on the slope stability solution.

In practice, it is therefore acceptable to provide steady-state pore pressures for each material for both drained, effective-stress and undrained, total-stress analyses. In each considered load case, pore pressures are computed to represent the steady-state seepage condition, prior to loading to failure (Section 6.1.9).

Table 15. Conditions for Drained versus Undrained Analyses

	Drained Condition	Undrained Condition	
Loading Cases (Section 5.1)	Long-Term	Pseudostatic Post-Earthquake	
Type of Stability Analysis	Effective Stress	Total Stress	
Pore Pressures at Failure	Assumed equal to steady state seepage	Unknown, cannot be predicted with confidence	
Characterization of Shear Strength	Drained, effective stress parameters	Undrained strength parameters	
Strength Parameters	c', ϕ'	S_u, ϕ = 0	c, ϕ or S_u/σ'_{vo}
Pore Pressures used in Stability Analysis	From steady state seepage model	Pore pressures not used	From steady state seepage model

6.1.9 Input Pore Pressures

The slope stability analyses require pore water pressures for computing effective consolidation stresses, as defined for the specified load conditions (Section 5.1). Pore pressures are predicted based on the depth below the assumed phreatic surface, sometimes called the piezometric line. This line illustrates the locations in the cross section at which the pore pressure is assumed to be zero. The pore pressure increases hydrostatically with distance below this line.

The pore water pressures in some stability analyses must be computed using piezometric lines. Due to software limitations, SLOPE/W cannot use mapped pressures from the SEEP/W solution for certain load cases.

A piezometric line is assumed to correspond to the phreatic line (line of zero pore pressure) predicted by SEEP/W. The phreatic line is manually digitized for input to SLOPE/W, which then computes pore pressures at any point based on the depth below this line. Some of the detailed information from the seepage analysis is thus lost because SLOPE/W cannot interpolate the nodal pore pressures from the finite element solution.

The less rigorous method, using piezometric lines to compute pore pressures, may or may not be conservative, depending on the geometry and details of the seepage problem. Little to no error occurs when seepage passes through a uniform cross section and the phreatic surface is horizontal. Greater inaccuracies are introduced when pore pressures are computed from more steeply sloping piezometric lines.

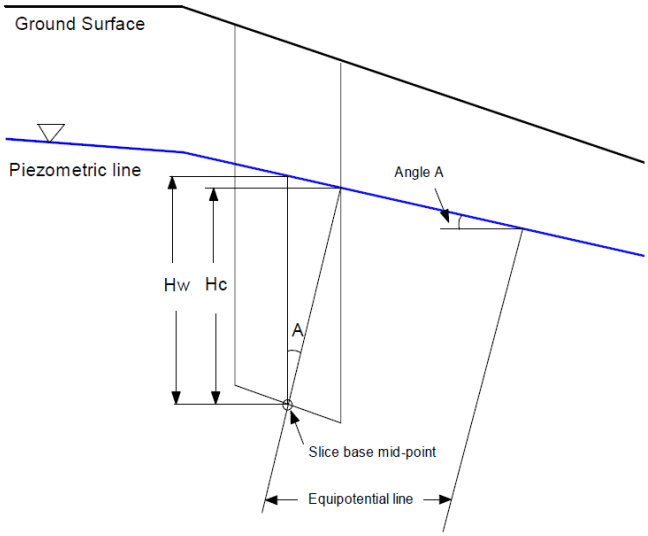
To reduce this error in the undrained analyses that use piezometric lines, an approximate "phreatic correction" is employed within SLOPE/W. Instead of computing pressures based on the vertical distance below the piezometric line, pore water pressures (u) are computed as (GEO-SLOPE 2015):

$$u = \gamma_w H_c = \gamma_w H_w \cos^2 A \qquad \textbf{Equation 3}$$

The unit weight of water is γ_w. The heights used to compute the pore pressure at the base center of the slice with and without correction are H_c and H_w, respectively. The variables in Equation 3 are further defined on Figure 19. The correction factor ($\cos^2 A$) is one for a horizontal phreatic surface (A = 0°) and approaches zero as the phreatic surface approaches vertical (A = 90°).

Pore water pressures above the phreatic line are assumed to be zero. That is, pore pressures within the unsaturated material are set to zero so that no additional soil strength along the slip surface is attributed to suction pressures (capillary tension).

Figure 19. Phreatic Surface Correction (from GEO-SLOPE 2015)



6.1.10 Composite Strength Envelopes in Undrained Analyses

Most soils will exhibit dilative shear behavior at low confining pressures. When saturated soils are consolidated to low effective stress and then sheared without drainage, the tendency to expand will cause decreasing pore pressures (suction). This results in increasing effective stress and shearing resistance, but the additional shear strength due to negative pore pressures may not be sustainable in the field. Hence, computed factors of safety for stability may be unconservative if some part of the slip surface has an undrained strength greater than the drained strength.

To avoid relying upon suction pressures for undrained shearing resistance, composite (bi-linear) drained-undrained strength envelopes (see Appendix E) are used in the undrained stability analyses. The undrained strength is then the lesser of the undrained or drained strength envelopes at any given normal stress. Composite strength envelopes are used for the undrained stability analyses, including the seismic stability analyses, as indicated in the summaries of the undrained strength parameters.

In SLOPE/W, composite or bi-linear strength envelopes are specified in terms of the intercept and friction angle of the drained strength branch, the friction angle of the undrained strength branch, and the transition normal stress (where the drained and undrained envelopes cross).

6.1.11 Single-Stage versus Multiple-Stage Analyses

In a single-stage slope stability analysis, the sliding resistance and factor of safety are computed concurrently, for a given failure surface, problem geometry, and applied load. This approach is correct when the soil mass consolidates under the loading conditions being evaluated for stability. Here, single-stage stability analyses are appropriate for the construction, normal operations, post-earthquake, and each of the drained, effective stress analyses. In each of these cases, the steady state seepage conditions and applied external loads occur under the same conditions (geometry and applied load) and can be modeled in one limit equilibrium calculation.

In the other undrained load cases, the soils in the slope consolidate under an initial set of conditions, and the factor of safety is desired for a later, different load condition. In a multiple-stage stability analysis, the sliding resistance is quantified in the first stage and the factor of safety is computed in subsequent stages of the calculation for a given slip surface (Duncan and Wright 2005). Multiple-stage stability analyses provide a more rigorous model of the stability conditions for the pseudostatic earthquake load cases.

Two-stage analyses are used for the pseudostatic load cases (Section 6.2). SLOPE/W implements these multi-stage calculations automatically. The effective consolidation stresses and pore water pressures are computed along a trial slip surface in the first stage of the calculation, without the applied pseudostatic forces. The undrained shear resistance along the slip surface is quantified based on these effective stresses. The factor of safety is then computed for the same trial slip surface in the second stage of the calculation, with the pseudostatic forces applied and no change in the computed shearing resistance.

6.2 SEISMIC STABILITY

6.2.1 Pseudostatic, Global Stability

Dynamic slope stability during an earthquake is evaluated using pseudostatic, limit equilibrium methods. A constant, uniform, horizontal pseudostatic force is applied to the materials in the slope to approximate the dynamic, inertial loads generated by seismic shaking.

The simple concept of a constant pseudostatic force does not adequately account for soil flexibility, degradation in soil strength during the earthquake, the effects of embankment geometry on the ground motions, and the very short duration of the acceleration peaks. These factors make it difficult to select a pseudostatic coefficient that will adequately represent the dynamic effects of an earthquake on an earth slope. Pseudostatic analyses are acceptable for screening-level evaluations of embankments or slopes, where the computed factors of safety can be used to judge if more detailed analyses are warranted. The results are generally invalid, however, for marginally stable slopes subjected to strong accelerations, when significant soil liquefaction is predicted, or when substantial slope deformations are expected.

Pseudostatic forces are applied only in the horizontal direction in the stability analyses. Vertical inertia is ignored, because vertical accelerations will tend to reduce (or increase, depending on the direction of motion) both the driving soil weight and the sliding resistance (Kramer 1996). In the analysis of a dam, the pseudostatic forces are applied in the assumed direction of incipient motion. That is, a pseudostatic, horizontal force acting in the downstream direction is applied when evaluating downstream stability. The

applied direction is upstream for upstream stability. Seismic shear stresses are not transmitted through a water column, so pseudostatic forces are not applied to ponded water above the ground surface (GEO-SLOPE 2015).

The pseudostatic analyses are run in SLOPE/W so that the shear strength along the slip surface is not altered by the pseudostatic forces. That is, a two-stage pseudostatic analysis (Section 6.1.11) is completed. Consolidation stresses and shear strength are computed in the first stage, without the pseudostatic forces, and the factor of safety is computed in the second stage with the pseudostatic forces applied.

Seismic strength parameters (Table 8) are used for each soil. Undrained soil strengths are reduced to 80% of the static undrained strength, to account for pore pressure buildup, some strain-softening, and strain incompatibility during the earthquake (Section 4.1.7). The contribution of suction pressures to shearing resistance is neglected by specifying composite drained-undrained strength envelopes (Section 6.1.10). For liquefied soils, residual strengths (Section 4.1.8) are conservatively applied in the pseudostatic stability analyses.

The pseudostatic force, which is applied to the centroid of each slice in the limit equilibrium stability analyses, is computed as:

$$F_h = \frac{a_h W}{g} = k_h W \qquad \textbf{Equation 4}$$

Here, F_h is the applied inertial force, a_h is the horizontal acceleration, W is the weight of soil in each slice, and g is the acceleration due to gravity. The horizontal pseudostatic coefficient (k_h) is a dimensionless ratio, or fraction of gravity, representing the horizontal acceleration due to shaking. The value of k_h is usually selected as a fraction of the peak horizontal ground acceleration (PGA, in g's).

Guidelines for selecting an appropriate pseudostatic coefficient (k_h) to evaluate seismic slope stability have been suggested by several authors:

- Terzaghi (1950) suggested using k_h = 0.10, 0.20, and 0.50 for "severe", "violent, destructive", and "catastrophic" earthquakes, respectively
- For dams, Marcuson (1981) suggested using k_h = (0.33 to 0.50) PGA, with consideration for potential amplification or deamplification of the ground motions due to the dynamic characteristics of the structure
- Hynes-Griffin and Franklin (1984) recommended using k_h = 0.50•PGA, where PGA is the maximum horizontal acceleration at the bedrock surface. Their method was calibrated to the results of deformation analyses, so that a pseudostatic factor of safety of one would correspond to acceptable displacements (about 1 meter or less).
- Several authors (Seed and Martin 1966; Seed 1979; Taniguchi and Sasaki 1986; Dakoulas and Gazetas 1986; and Krinitzsky et al. 1993) showed that the value of k_h for an earth dam is a

function of the size of the sliding mass. They suggested k_h = PGA for a small sliding mass, k_h = 0.65 PGA for an intermediate sliding mass, and k_h = 0.10 to 0.15 for a large sliding mass.

- Kramer (1996) indicated that the Hynes-Griffin and Franklin (1984) method is appropriate for most slopes, but that the seismic coefficient should be based on the actual anticipated level of acceleration in the soil mass being evaluated, taking into account the effects of amplification or deamplification within the slope

- Kavazanjian et al. (1997) recommend using k_h = 0.17 PGA if a ground response analysis is performed, and k_h = 0.50 PGA if a ground response analysis is not performed. In this case, they use PGA computed at the ground surface, at the top of the slope.

For this stability evaluation, the pseudostatic coefficient is estimated based on the results of a Newmark sliding block analysis as defined in Appendix F. That is, the pseudostatic coefficient is taken as the yield acceleration corresponding to a Newmark displacement equal to the tolerable displacement (36 inches for this stability evaluation, per Section 5.1).

The procedure is as follows:

- A pseudostatic slope stability analysis is conducted, with the horizontal acceleration coefficient adjusted until a sliding factor of safety of one is obtained (FS=1). The critical failure surface from this analysis defines the slide mass and failure surface used in the subsequent step.

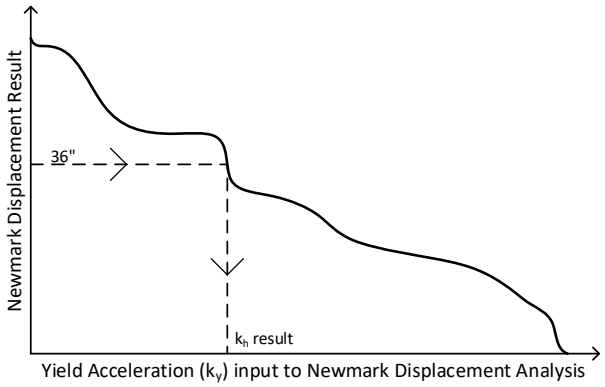
- Using the failure surface from the previous step, the ground motion time history is converted to a Horizontal Equivalent Acceleration (HEA) time history as described in Appendix F using Ground Response Analysis

- The Newmark displacement calculation is performed for the HEA time history repeatedly, using a different value of the yield acceleration each time. The results are plotted on a figure similar to Figure 20.

- From the plot produced in the proceeding step, the yield acceleration corresponding to a displacement of 36 inches is selected as the pseudostatic coefficient.

One value of k_h is obtained from each ground motion time history. However, pseudostatic stability analyses are needed only for the maximum value of k_h, as lower values of k_h will result in higher calculated factors of safety. For each earthquake load case (scenario event), k_h is obtained for each time history, and the maximum of these values is then used in the pseudostatic stability analyses.

Figure 20. Example plot of Newmark displacement versus yield acceleration



In the Newmark analysis, residual strength parameters were conservatively applied to the liquefied soils throughout the duration of the earthquake. In reality, soil shear strength would decrease from the drained strength to the residual strength as the earthquake progressed and pore water pressures accumulate.

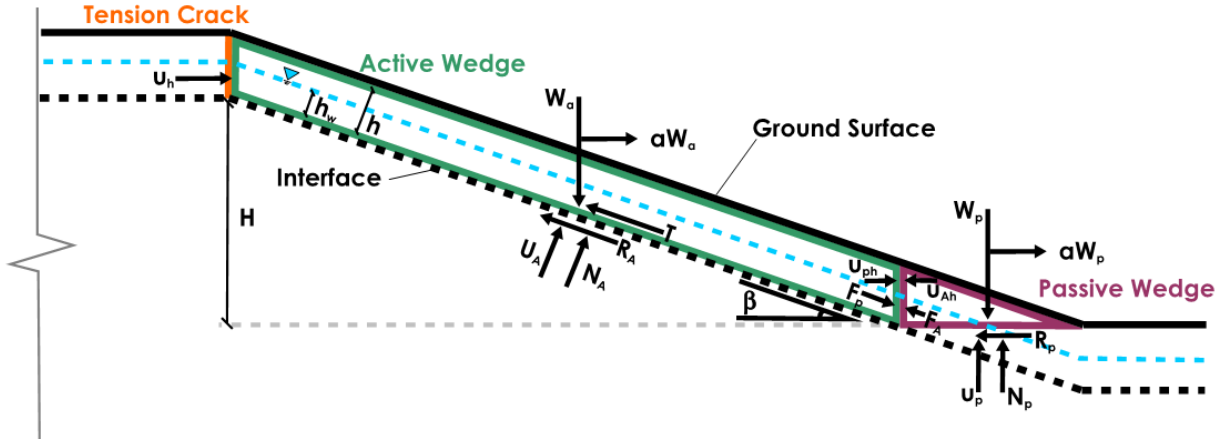
The predicted slope displacements are conservatively high because the yield acceleration is computed with reduced, undrained soil strengths for unliquefied materials and residual strengths for liquefied materials. The displacement analysis assumes liquefaction has already triggered at the start of the earthquake. In reality, the yield acceleration declines in successive cycles of seismic loading, as pore pressures accumulate and saturated soils become weaker. The analysis outlined here assumes reduced strengths at the start of the earthquake, so the computed yield acceleration is lower than the initial value in the slope. This results in conservatively larger predictions of displacements. Given the approximations involved in this simplified method of analysis, a more complex treatment of the yield acceleration is not warranted.

6.2.2 Pseudostatic, Veneer Stability

Veneer stability analyses were used to assess the potential for sliding in the cap system of the CCR unit. The geometry of the veneer stability problem is relatively simple and can be represented with a series of force balance equations.

An equation for the factor of safety for veneer stability was developed following the procedures outlined in Koerner and Soong (2005). A free body diagram (Figure 21) illustrates the forces considered in the analysis. The derivation and definitions of the variables used in the veneer stability derivation are provided in Section 2.0 of Appendix C.

Figure 21. Free body diagram representing veneer stability problem



The veneer stability analysis is a pseudostatic analysis when a nonzero value is used for the lateral acceleration, a. The nonzero value for the lateral acceleration at the base of the Cover Material was determined per the following process, which is further detailed in Appendix C.

The ground response analyses discussed in Section 5.3 and Appendix D were used to determine a pseudostatic acceleration for the veneer stability analysis of the cover system. The ground response analysis results (from Appendix D) for vertical profiles that pass through the midslope of the East Dike, were used. The computed accelerations at the base of the cover system were examined.

The peak acceleration at the base of the cover layer was selected, for each of the input ground motions that were analyzed. The maximum of all computed peak accelerations was selected. The peak acceleration is a very short duration, high frequency pulse. To obtain a reasonable indication of the seismic force, the lateral acceleration (a) used in the pseudostatic veneer stability analysis was assumed to be 65% of the peak acceleration at the base of the cover layer.

6.2.3 Liquefaction Triggering

The methodology employed to predict liquefaction triggering is described in Appendix F.

6.2.4 Post-Earthquake, Global Stability

Stability is also evaluated for the static conditions immediately following the cessation of the earthquake motions. No pseudostatic forces are applied. Residual or steady state strengths are assigned in zones where soil liquefaction is predicted (Appendix F).

The seismic strength parameters summarized in Table 8 and Table 10 are specified for unliquefied and liquefied soils, respectively. For unliquefied soils, the undrained strengths are reduced to 80% of the static undrained strength, to account for cyclic softening and pore pressure buildup during the earthquake. The contribution of suction pressures to shearing resistance is neglected by specifying composite drained-undrained strength envelopes (Section 6.1.10).

7.0 RESULTS

The global stability results presented (and compared to the acceptance criteria) are those in which the critical failure surface intercepts the contained CCR within the unit (See Section 6.1.5). The global stability analysis models and critical failure surfaces are shown in Appendix B. Calculations for the veneer stability results presented below are included in Appendix C.

7.1 SEISMIC STABILITY

The seismic stability analyses presented below are the lowest sliding factors of safety of the two design earthquake scenarios considered: the one Hz and 10 Hz scenarios.

The pseudostatic, global stability and post-earthquake, global stability were analyzed for each cross section. The pseudostatic, veneer stability was analyzed for the typical geometry of the cover system. The results of the seismic stability analyses, with the minimum required FS for each case, are summarized in Table 16.

Table 16. Seismic Stability Results at KIF Plant

CCR Unit	Analysis Type	Cross Section	FS Required[1]	FS Sliding[1]
Sluice Trench and Ballfield East of Sluice Trench	Pseudostatic, Global	A-A'	≥ 1.0	< 1.0 (see discussion below)
Sluice Trench and Ballfield East of Sluice Trench	Pseudostatic, Global	Polishing Pond	≥ 1.0	< 1.0 (see discussion below)
Sluice Trench and Ballfield East of Sluice Trench	Pseudostatic, Veneer	Typical	≥ 1.0	1.0
Sluice Trench and Ballfield East of Sluice Trench	Post-Earthquake, Global	A-A'	≥ 1.0	1.0
Sluice Trench and Ballfield East of Sluice Trench	Post-Earthquake, Global	Polishing Pond	≥ 1.0	0.8

1. Required and calculated FS for Factor of Safety from Phase 2 assessment

The ability to compute a factor of safety for the pseudostatic case is first dependent on the slope being stable (FS Sliding ≥ 1.0) with no seismic loading ($k_h = 0$). Recall that in the Newmark analysis (Section 6.2.1), residual strength parameters were conservatively applied to the liquefied soils throughout the duration of the earthquake. Thus, the post-earthquake case ($k_h = 0$) conservatively represents the starting condition for the pseudostatic case. For the Polishing Pond section, the post-earthquake FS is less than 1.0, thus a valid yield acceleration cannot be computed for the Newmark analysis and the displacement is inferred to exceed the tolerable value of three ft. For Section A-A', the post-earthquake FS is 1.0 and the yield acceleration therefore is zero. Given the design earthquake accelerations, the displacement is inferred to exceed the tolerable value of three ft. As defined herein, Newmark displacements in excess of three ft correlate to pseudostatic FS less than 1.0.

7.1.1 Liquefaction and Cyclic Softening Triggering Evaluations

Each material, excluding the Riprap, Filter Materials, Gravel Residuum, and Cover Material, was first evaluated to determine whether the material was characteristically sand-like or clay-like using CPT, SPT, and laboratory data. The Riprap, Filter Materials, Gravel Residuum, and Cover Material were not evaluated because these materials are either free draining (Riprap and Filter Materials), too dense to liquefy (Gravel Residuum), or unsaturated (Cover Material).

Laboratory testing results indicate that the Bottom Ash, Fly Ash, Subunit 2, and Subunit 3 are sand-like materials. CPT data was also used to evaluate whether the material is sand-like or clay-like using criteria from Robertson (2008), where CPT data is placed into one of four zones, shown in Section 3.4 of Appendix D. The Bottom Ash CPT data indicated equal proportions of clay-like and sand-like samples; 50% of samples were sand-like based on the Robertson criteria. A large proportion of the Fly Ash CPT samples, 84%, were found to be sand-like. Subunit 2 had near equal proportions of sand-like and clay-like samples based on the CPT data, 48% of samples were sand-like. A large portion of the CPT data for Subunit 3, 91% of samples, were sand-like, similar to the laboratory testing results.

Liquefaction triggering was assessed using the process outlined in Appendix F. Using this process, the materials predicted to liquefy extensively at both cross sections in the Sluice Trench and Ballfield East of Sluice Trench during the design earthquakes are the Fly Ash and Subunit 3. As discussed in Section 4.1.8, the Sediment is also assumed to liquefy. Results are summarized in Table 17, and are accounted for in the pseudostatic and post-earthquake, global stability analyses.

The Embankment Fill and Subunit 1 were clay-like materials based on laboratory testing results. The CPT data indicated that the Embankment Fill had near equal proportions of sand-like and clay-like material, where 49% of the samples were clay-like. The CPT data for Subunit 1 indicated a similar proportion of clay-like samples as the laboratory testing, where 99% of the CPT samples were clay-like. A summary of the clay-like and sand-like determination for the materials is presented previously in Table 9 (Section 4.1.8). Cyclic softening is not predicted to occur in the clay-like materials, Subunit 1 and the Embankment Fill, for the design earthquakes. Results are summarized in Table 17, and are accounted for in the pseudostatic and post-earthquake, global stability analyses.

Table 17. Liquefaction Triggering Results at KIF Plant

CCR Unit	Cross Section	Liquefaction Predicted?	Cyclic Softening Predicted?
Sluice Trench and Ballfield East of Sluice Trench	A-A’	Yes, in Fly Ash, Subunit 3, and Sediment	None
Sluice Trench and Ballfield East of Sluice Trench	Polishing Pond	Yes, in Fly Ash, Subunit 3, and Sediment	None

8.0 VARIATIONS

The proposed scope and procedures for the stability analysis were outlined in the SAP and QAPP, as detailed in the sections above. Variations in scope or procedures discussed with TDEC and/or TVA are described in the following sections. As discussed below, these variations do not impact the overall usability and representativeness of the dataset provided in this SAR for the stability analysis activities at the KIF Plant.

8.1 VARIATIONS IN SCOPE

No variations in scope occurred during stability analysis activities.

8.2 VARIATIONS IN PROCEDURES

Variations in procedures occurring during the stability analysis are provided below.

- This SAR summarizes activities completed to meet the objectives of the Stability SAP (Stantec 2018a), for applicable seismic load cases. Static load cases (if any) required by the SAP are documented in a separate Static Stability SAR. This change in procedure was approved by TDEC.

9.0 SUMMARY

The objective of this study was to document the execution of the seismic stability analyses, conducted pursuant to the Stability SAP (Stantec 2018a), and to serve as part of the underlying basis for the EAR. The SAP specified how new and updated global and veneer stability analyses for the Sluice Trench and Ballfield East of Sluice Trench should be developed. Static load cases (if any) required by the SAP are documented in a separate Static Stability SAR.

The stability analyses performed as part of this SAR include pseudostatic, global and veneer stability analyses and post-earthquake, global stability analyses performed in accordance with the methods outlined in the SAP. These analyses were performed at two representative global stability cross sections and one representative veneer cross section at the Sluice Trench and Ballfield East of Sluice Trench.

The seismic stability results for the KIF Plant are summarized and compared to criteria in Table 16. The veneer stability for the typical section meets the established factor of safety criteria for the pseudostatic load case. In this Phase 2 assessment, the global stability results of both cross sections are below the established factor of safety criteria for the pseudostatic and post-earthquake load cases. The global pseudostatic and post-earthquake stability results are primarily driven by the liquefaction potential and residual strengths within the foundation soil subunits, which can be evaluated further in Phase 3 and Phase 4 assessments as described below.

Phase 2 stability analyses, as defined in the Stability SAP, were performed for each defined section and case. The analyses employed available site information, including additional Exploratory Drilling data, and simplified analysis methods. For cases meeting acceptance criteria, no subsequent phases of stability analysis are required. For cases not meeting acceptance criteria, Phase 3 and Phase 4 assessments may be appropriate, per the Stability SAP. A Phase 3 assessment may include a nonlinear deformation analysis to estimate displacements due to the design earthquake. A Phase 4 assessment considers the consequences (impacts to human health and/or environment) of the predicted deformations (from Phase 3).

Instead of pursuing the Phases 3 and 4 of analysis of the existing conditions, TVA has elected to pursue seismic mitigation of the Sluice Trench and Ballfield East of Sluice Trench. TVA is currently evaluating mitigation alternatives that would be designed to meet the seismic stability acceptance criteria as defined in the Stability SAP. This path forward will be noted in the EAR, and it is anticipated that the mitigation design process will commence in parallel with the Corrective Action/Risk Assessment phase of the TDEC Order program.

Stantec has completed the Phase 2 seismic stability analyses at the KIF Plant in Harriman, Tennessee, in accordance with the Stability SAP as documented herein. The results are usable for reporting and evaluation in the EAR and meet the objectives of the TDEC Order EIP. The results will be evaluated along with data collected under other TDEC Order SAPs, as well as other State and CCR programs. This evaluation will be provided in the EAR.

APPENDIX B – GLOBAL STABILITY ANALYSIS RESULTS

Summary of Global Slope Stability Analyses and Results - KIF - Sluice Trench and Ballfield East of Sluice Trench (Closed Condition)

Cross Section	Load Case	Pool Levels	Incipient Motion	Analysis	Soil Strengths	Pore Pressures	Slope Stability Analysis Results			
							Dmin=10' & CCR Intercept		Dmin=10'	
							Acceptance Criteria	Factor of Safety for Sliding (FS)	Acceptance Criteria	Factor of Safety for Sliding (FS)
Section A-A'	Pseudostatic	Adjacent Reservoir: Winter Pool	Outboard	Undrained Seismic	Undrained Seismic; Residual Strengths in Liquefied Materials	Piezometric Line	FS ≥ 1.0	< 1.0 (see note)	N/A	< 1.0 (see note)
	Post-Earthquake			Undrained Static	Undrained Seismic; Residual Strengths in Liquefied Materials		FS ≥ 1.0	1.0	N/A	1.0
Polishing Pond	Pseudostatic	Adjacent Reservoir: Winter Pool	Outboard	Undrained Seismic	Undrained Seismic; Residual Strengths in Liquefied Materials	Piezometric Line	FS ≥ 1.0	< 1.0 (see note)	N/A	< 1.0 (see note)
	Post-Earthquake			Undrained Static	Undrained Seismic; Residual Strengths in Liquefied Materials		FS ≥ 1.0	0.8	N/A	0.8

Note: The ability to compute a factor of safety for the pseudostatic case is first dependent on the slope being stable (FS Sliding ≥ 1.0) with no seismic loading (kh = 0). In the Newmark analysis, residual strength parameters were conservatively applied to the liquefied soils throughout the duration of the earthquake. Thus, the post-earthquake case (kh = 0) conservatively represents the starting condition for the pseudostatic case. For Section A-A', the post-earthquake FS is 1.0 and the yield acceleration therefore is zero (ky = 0 g). Given the design earthquake accelerations, the displacement is inferred to exceed the tolerable value of 3 feet. For the Polishing Pond section, the post-earthquake FS is less than 1.0, thus a valid yield acceleration cannot be computed for the Newmark analysis and the displacement is inferred to exceed the tolerable value of 3 feet. Newmark displacements in excess of 3 feet correlate to pseudostatic FS less than 1.0.

Kingston Fossil Plant (KIF) TDEC Order	**Slope Stability Analysis – FS = 1.0**	Note: The results of the analysis shown here are based on available subsurface information, laboratory test results and approximate soil properties. The drawing depicts approximate subsurface conditions based on historical drawings or specific borings at the time of drilling. APPENDIX C – VENEER STABILITY ANALYSIS RESULTS

Tennessee Valley Authority Kingston Fossil Plant Kingston, Roane County, Tennessee	Sluice Trench and Ballfield East of the Sluice Trench

Appendix C
Veneer Stability Analyses

Purpose:

- Analyze stability of the cover system (cap) for the Sluice Trench and Ballfield East of the Sluice Trench.
- Estimate interface strength parameters (adhesion and friction angle) for the cover materials to support the stability analysis.

Methods:

- Consider veneer (infinite slope) stability failure mode for the cover system.
- Use the method developed by Koerner and Soong (2005).

Results:

- The veneer stability of the cap system is compared against the target FS value for a pseudostatic case.

Calculation Performed by: Stantec Consulting Services Inc.	
Prepared by: Nick Duda	*Reviewed by:* Jeff Dingrando
Date: 7/6/2021	

1. STABILITY CRITERIA

The stability of the cover system was analyzed for the conditions summarized in Table 1, as defined in the SAP. The associated acceptance criteria for minimum factor of safety (FS) are listed in the last column.

Table 1. Summary of Veneer Stability Cases and Design Criteria

Design Condition	Interface Strength	Cover Soil Strength	Saturated/ Unsaturated	Static/ Pseudostatic	Criteria for Slope Stability
Seismic	Peak	Drained	Unsaturated	Pseudostatic	FS > 1.0

2. ANALYSIS METHODOLOGY

Veneer stability analyses were used to assess the potential for sliding in the cap system. The geometry of the veneer stability problem is relatively simple and can be represented with a series of force balance equations.

An equation for the factor of safety for veneer stability was developed following the procedures outlined in Koerner and Soong (2005). The derivation follows. A free body diagram (Figure 1) illustrates the forces considered in the analysis. Definitions of the variables used in the veneer stability derivation are provided in Table 2.

Table 2. Definition of Variables for Veneer Stability Derivation

Variable	Description
W_A	Total weight of the active wedge
W_P	Total weight of the passive wedge
N_A	Effective force normal to the active wedge failure plane
N_P	Effective force normal the passive wedge failure plane
h	Thickness of the cover soil
H	Height of the slope
β	Slope angle
a	Horizontal acceleration
u_h	Resultant of the pore pressures acting in the tension crack
u_A	Resultant of the pore pressures acting perpendicular to the slope
u_p	Resultant of the pore pressures acting perpendicular to the bottom on the passive wedge
u_{ph}	Resultant of the pore pressures acting on the inter-wedge surface to the passive wedge
u_{Ah}	Resultant o the pore pressures acting on the inter-wedge surface to the active wedge
h_w	Water height measured in the direction perpendicular to the slope
R_A	Resistance along the bottom of the active wedge
R_P	Resistance along the bottom of the passive wedge
F_A	Inter-wedge force acting on the active wedge from the passive wedge
F_P	Inter-wedge force acting on the passive wedge from the active wedge
T	Reinforcement
c_c	Cohesion of the cover soil
ϕ	Friction angle of the cover soil
γ	Moist unit weight of the cover soil
γ_{sat}	Saturated unit weight of the cover soil
Δγ	Difference between saturated and moist unit weight of the cover soil
c_a	Adhesion of the interface
δ	Friction angle of the interface
FS	Factor of safety
A, B, C, D, L, M, N	Arbitrary variables to simplify final equations

For the active wedge:

$$W_A = \left(\frac{H}{\sin\beta}\right) h_w \gamma_{sat} + \left(\frac{H}{\sin(\beta)}\right)(h - h_w)\gamma$$

$$W_A = \left(\frac{H}{\sin\beta}\right)(h_w \gamma_{sat} + h\gamma - h_w \gamma)$$

$$W_A = \left(\frac{H}{\sin\beta}\right)(h_w \Delta\gamma + h\gamma) \qquad \textbf{Equation 1}$$

$$u_h = \frac{1}{2}(\gamma_w h_w \cos\beta)\left(\frac{h_w}{\cos\beta}\right) = \frac{1}{2}\gamma_w {h_w}^2 \qquad \textbf{Equation 2}$$

$$u_{Ah} = \frac{1}{2}(\gamma_w h_w \cos\beta)\left(\frac{h_w}{\cos\beta}\right) = \frac{1}{2}\gamma_w {h_w}^2 = u_h \qquad \textbf{Equation 3}$$

$$u_A = (\gamma_w h_w \cos\beta)\left(\frac{H}{\sin\beta}\right) = \frac{\gamma_w h_w H}{\tan\beta} \qquad \textbf{Equation 4}$$

Considering force balance in the direction perpendicular to the slope:

$$N_A = W_A \cos\beta - aW_A \sin\beta - u_A - u_h \sin\beta + u_{ah} \sin\beta$$

$$N_A = W_A(\cos\beta - a\sin\beta) - u_A \qquad \textbf{Equation 5}$$

$$R_A = N_A \tan\delta + \frac{c_a H}{\sin\beta} \qquad \textbf{Equation 6}$$

Considering force balance in the direction parallel to the slope:

$$F_A = u_h \cos\beta + W_A \sin\beta + aW_A \cos\beta - u_{Ah} \cos\beta - \frac{R_a}{FS} - T$$

$$F_A = W_a(\sin\beta + a\cos\beta) - \frac{R_a}{FS} - T \qquad \textbf{Equation 7}$$

For the passive wedge:

$$W_p = \left(\frac{h}{\cos\beta}\right)\left(\frac{h}{\sin\beta}\right)\frac{\gamma}{2} + \left(\frac{h_w}{\cos\beta}\right)\left(\frac{h_w}{\sin\beta}\right)\frac{\Delta\gamma}{2}$$

$$W_p = \frac{h^2\gamma + {h_w}^2 \Delta\gamma}{\sin 2\beta} \qquad \textbf{Equation 8}$$

$$u_p = \frac{1}{2}(\gamma_w h_w \cos\beta)\left(\frac{h_w}{\sin\beta}\right) = \frac{\gamma_w {h_w}^2}{2\tan\beta} \quad \textbf{Equation 9}$$

$$u_{ph} = \frac{1}{2}(\gamma_w h_w \cos\beta)\left(\frac{h_w}{\cos\beta}\right) = \frac{1}{2}\gamma_w {h_w}^2 \quad \textbf{Equation 10}$$

Considering force balance in the vertical direction

$$N_p = W_p + F_p \sin\beta - u_p \quad \textbf{Equation 11}$$

$$R_p = N_p \tan\varphi + c_c \frac{h}{\sin\beta} \quad \textbf{Equation 12}$$

Considering force balance in the horizontal direction

$$F_p \cos\beta + u_{ph} + aW_p = \frac{R_p}{FS}$$

$$FS\left(F_p \cos\beta + u_{ph} + aW_p\right) = \left(W_p + F_p \sin\beta - u_p\right)\tan\varphi + c_c \frac{h}{\sin\beta}$$

$$F_p(FS\cos\beta - \sin\beta\tan\varphi) = \left(W_p - u_p\right)\tan\varphi + c_c \frac{h}{\sin\beta} - FS\left(u_{ph} + aW_p\right)$$

$$F_p = \frac{\left(W_p - u_p\right)\tan\varphi + c_c \frac{h}{\sin\beta} - FS\left(u_{ph} + aW_p\right)}{FS\cos\beta - \sin\beta\tan\varphi} \quad \textbf{Equation 13}$$

Let $F_A = F_p$, then:

$$W_a(\sin\beta + a\cos\beta) - \frac{R_a}{FS} - T = \frac{\left(W_p - u_p\right)\tan\varphi + c_c \frac{h}{\sin\beta} - FS\left(u_{ph} + aW_p\right)}{FS\cos\beta - \sin\beta\tan\varphi} \quad \textbf{Equation 14}$$

Let also:

$$A = W_a(\sin\beta + a\cos\beta) - T \quad \textbf{Equation 15}$$

$$B = \left(W_p - u_p\right)\tan\varphi + c_c \frac{h}{\sin\beta} \quad \textbf{Equation 16}$$

$$C = u_{ph} + aW_p \quad \textbf{Equation 17}$$

$$D = \sin\beta\tan\varphi \quad \textbf{Equation 18}$$

Then Equation 14 becomes:

$$A - \frac{R_a}{FS} = \frac{B - FS * C}{FS\cos\beta - \mathrm{D}}$$

$$\frac{A * FS - R_a}{FS} = \frac{B - FS * C}{FS\cos\beta - \mathrm{D}}$$

$$A\cos\beta\, FS^2 - A * D * FS - R_a\cos\beta\, FS + R_a D = B * FS - C * FS^2$$

$$(A\cos\beta + C)FS^2 - (AD + B + R_a\cos\beta)FS + R_a D = 0 \qquad \textbf{Equation 19}$$

Let:

$$L = A\cos\beta + C \qquad \textbf{Equation 20}$$

$$M = AD + B + R_a\cos\beta \qquad \textbf{Equation 21}$$

$$N = R_a D \qquad \textbf{Equation 22}$$

Then Equation 19 becomes:

$$L * FS^2 - M * FS + N = 0$$

$$FS = \frac{M + \sqrt{M^2 - 4LN}}{2L} \qquad \textbf{Equation 23}$$

Here, FS is the factor of safety for veneer sliding within the cap.

3. ANALYZED CONDITONS

3.1. COVER GEOMETRY

The final cover system (cap) on the Sluice Trench and Ballfield East of the Sluice Trench was constructed with soil and geosynthetic materials overlying CCR (labeled CCP in historical drawings) materials, having an overall thickness of 2.0 feet. The constructed cap system is shown in Figure 2 (AECOM 2019). The veneer stability was evaluated at the steepest section within the unit, along the Polishing Pond section, with the 2.0 feet of soil above the geosynthetic components, where the mid-slope angle is 10˚ and mid-slope height of 11.2 feet above the access road.

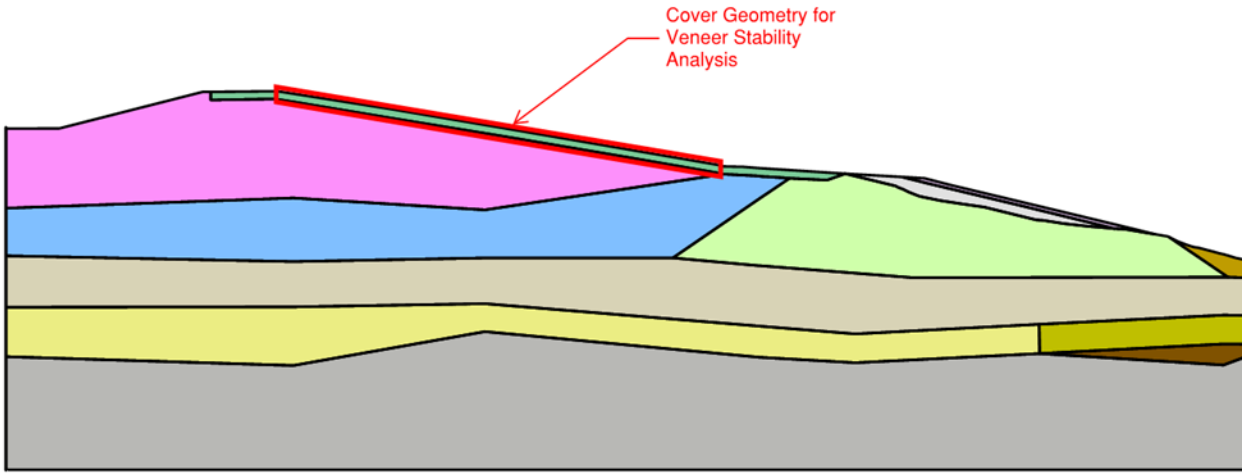

Figure 2. Selected geometry for Veneer Stability analyses

This analysis serves to evaluate the interface strengths encountered in the cap system. The results presented here apply to these interfaces (i.e., whichever has the lowest strength):

- Cover soil (internal shear strength, just above the geosynthetics)
- the cover soil/geocomposite drainage layer interface
- the geocomposite drainage layer/LLDPE textured geomembrane interface
- the LLDPE textured geomembrane/CCR material interface
- CCR (internal shear strength, just below the geosynthetics)

The interface strengths of the various materials in the cap system were evaluated to identify the critical interface and then compute the veneer factor of safety.

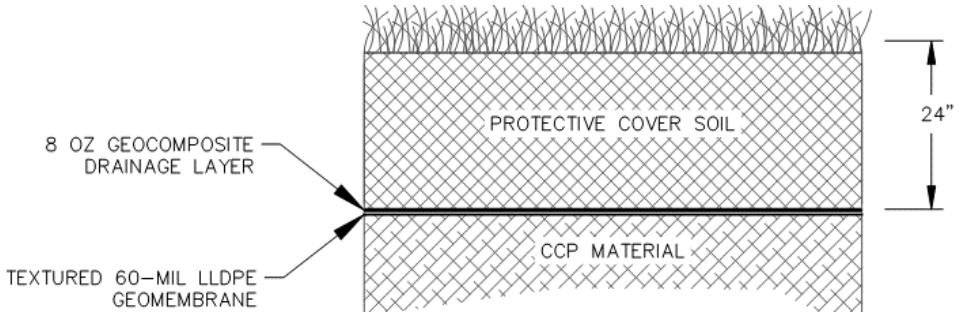

Figure 3. Cap System Constructed at the Sluice Trench and Ballfield East of the Sluice Trench (AECOM 2019)

3.2. COVER SOIL PARAMETERS

Values for the drained shear strength, moist unit weight, and saturated unit weight of the cover soil are required to perform the veneer stability analyses. Estimated parameters for the cover soil are summarized in Table 3.

The cover soil was sourced from the ”I-40 borrow area” and generally classified as fat clay with sand (CH), as detailed in the construction certification report for the closure of the unit in 2016 (AECOM 2016). It is assumed that similar material was used for the cover soil in the 2019 East Dike Area Closure.

Moist and saturated unit weights for the cover soil were estimated from available lab testing results. See Section 4.1 of the SAR for additional details.

For the veneer stability analysis, the drained shear strength parameters for the cover soil were estimated based on typical values from NAVFAC (1986) (see Figure 3 in Appendix D). Additionally, it is assumed that the Cover Material and CCR underlying the cap have no adhesion.

Table 3. Cover Soil Parameter Summary

Parameter	Value
Drained Friction Angle	19˚
Drained Cohesion	0 psf
Moist Unit Weight	120 pcf
Saturated Unit Weight	121 pcf

3.3. GEOSYNTHETIC PARAMETERS

The cover system constructed at the Sluice Trench and Ballfield East of the Sluice Trench was not evaluated for veneer strength prior to construction, likely due to the unit being relatively flat. It is assumed that the geocomposite/geomembrane interface is the weakest (i.e., most critical) of the above listed interfaces within the cap system.

Per the construction certification report for the closure of the East Dike, the geomembrane and geocomposite products used in the cap were the Agru 60-mil Microspike LLDPE and SKAPS Transnet HDPE Geocomposite with TN 330 Geonet (8 oz/yd^2) (AECOM 2019). No product-specific strength data was available in the construction report. In order to estimate the interface strength of the geocomposite/geomembrane interface, a literature review was conducted.

To estimate the geocomposite/geomembrane interface shear strength, a selection of studies was used to estimate the interface strength (Pavanello *et al.* 2018, Akpinar and Benson 2005, Stark *et al.* 1996, Bacas *et al.* 2015). Some of the geosynthetic interfaces evaluated in these papers were comparable to the interfaces within the cap system at KIF. The manufacture sheets for the installed geomembrane and geocomposite were used to compare the material type, asperity height, density, and thickness of the installed materials to those evaluated in the referenced studies. Based on the manufacture sheet, the Agru 60-mil LLDPE geomembrane has a nominal thickness of 1.5 mm and an asperity height of 0.51 mm. The SKAPS Transnet HDPE Geocomposite with TN 330 Geonet is composed of a nonwoven geotextile heat bonded with the geonet and geotextile with a mass per unit area of 8 oz/yd^2, or 270 g/m^2.

- Pavanello *et al.* (2018) evaluated the static interface angle of textured HDPE geomembrane and nonwoven geotextile as part of their investigation of the dynamic friction and seismic performance of various geosynthetic interfaces. The thickness of the textured geomembrane evaluated was 1.5

mm and the nonwoven geotextile evaluated had a mass per unit area of 300 g/m^2. The average, static interface friction angle for the geotextile/geomembrane interface was measured to be about 24˚.

- Akpinar and Benson (2005) evaluated the shear strength of interfaces between nonwoven geotextiles and HDPE geomembranes, including a textured geomembrane, as part of their investigation. The textured geomembrane evaluated had an asperity height of 0.25 mm, and the geotextile evaluated has a mass per unit area of 270 g/m^2. Although asperity height of the geomembrane evaluated is approximately half of height for the installed geomembrane, the system as a whole compares well to the interface within the cap system at the Sluice Trench and Ballfield East of the Sluice Trench. The interface friction angle for the geotextile/geomembrane interface was measured to be approximately 26˚.

- Stark *et al.* (1996) evaluated multiple geosynthetic interfaces, including a co-extruded geomembrane and geocomposite composed of nonwoven geotextile and thermally bonded geonet. The geomembrane evaluated had an asperity height of 0.45 mm and nominal thickness of 1.5 mm. The mass per unit area of the geocomposite evaluated was 270 g/m^2. It was found that the presence of the geonet did not significantly increase the interface shear resistance compared to the textured geomembrane/nonwoven geotextile interface, and the interface friction angle was estimated to be 30˚.

- Bacas *et al.* (2015) evaluated multiple geomembrane/geocomposite interfaces as part of their investigation of frictional behavior of typical geosynthetic interfaces. The interface evaluated most similar to the geocomposite/geomembrane interface within the cap system is a textured geomembrane, with an asperity height of 0.5mm, and a geocomposite composed of nonwoven 200 and 300 g/m^2 geotextile thermally bonded to the geonet. The 300 g/m^2 geotextile face of the geocomposite was placed on top of the geomembrane for the evaluation of the interface friction. The interface friction angle for this interface was found to be 16˚.

Considering all of the above published parameters, the interface friction suggested by Bacas *et al.* of 16˚ was selected as representative for the interface friction of the geomembrane/geocomposite interface within the cap system at KIF. This value was selected because the materials within the study were similar to those used in the cap system, and that this value represented the most conservative choice, as Pavanello *et al.* (2018), Akpinar and Benson (2005) and Stark *et al.* (1996) indicate the value may be much higher.

3.4. SUBGRADE PARAMETERS

Values for the drained shear strength, moist unit weight, and saturated unit weight of the two subgrade materials (Fly Ash and Bottom Ash) are required to perform the veneer stability analyses. The parameters for the subgrade materials are summarized in Table 4.

The drained shear strength parameters for the Fly Ash and Bottom Ash were derived from Exploratory Drilling SAR and historical consolidated undrained (CU) triaxial compression laboratory testing results. The moist unit weight and saturated unit weight values were determined from Exploratory Drilling SAR and historical laboratory testing data. The material parameter selection is detailed in Section 4 of the Static Stability SAR.

Table 4. Subgrade Parameter Summary

Material	Drained Friction Angle (degrees)	Drained Cohesion (psf)	Moist Unit Weight (pcf)	Saturated Unit Weight (pcf)
Fly Ash	34	0	112	112
Bottom Ash	37	0	119	124

3.5. SELECTED INTERFACE FOR VENEER ANALYSIS

Based on parameters provided in Section 3.2 through Section 3.4, the weakest (i.e., most critical) zone of the cap system is the interface friction angle of the geomembrane/geocomposite interface.

3.6. PSEUDOSTATIC ACCELERATION

To model seismic stability in the cover, a pseudostatic acceleration (a) is applied as shown in the Koerner and Soong (2005) equations in Section 2.

Ground response analyses were completed to develop ground motion time histories for use in the pseudostatic global stability and liquefaction triggering analyses (Appendix D). These same ground response analyses were used here to determine a pseudostatic acceleration for the veneer stability analysis of the cover system.

The Strata results (from Appendix D), for vertical profiles that pass through selected portion of the Polishing Pond Section (Figure 2), were used. The computed accelerations at the base of the cover system were examined.

The peak accelerations at the base of the cover layer for each input ground motion were analyzed. The peak accelerations for the 1 Hz scenario ground motions were averaged. Separately, the peak accelerations for the 10 Hz scenario ground motions were averaged. Then the greater of the two averages (either the 1 Hz average or the 10 Hz average) was selected as the peak acceleration. However, the peak acceleration is a very short duration, high frequency pulse. To obtain a reasonable indication of the seismic force, the pseudostatic acceleration was assumed to be 65% of the peak acceleration.

For the twenty input ground motions (13 motions for the 10 Hz scenario and seven motions for the 1 Hz scenario), the ground response analyses predicted an average peak acceleration at the base of the cover of 0.191 g for the 10 Hz motions and 0.096 g for the 1 Hz motions. The pseudostatic acceleration selected for use in the analysis (a = 0.124 g) is 65% of the larger of the two average peak acceleration values (65% of 0.191 g).

4. ANALYSIS RESULTS

The calculations for each design condition are presented at the end of this appendix.

4.1. SEISMIC CASE

Applying the minimum interface strength within the cap system (Section 3.5), the pseudostatic case has a factor of safety of 1.0.

1 INTRODUCTION

This appendix contains information pertaining to the ground response analysis, liquefaction and cyclic softening analysis, and residual strength derivation.

Information supporting the ground response analysis is in Section 2. Section 2.1 contains plots of shear wave velocity data versus mean effective stress. These plots are used to develop characteristic models for each material in the ground response analysis. Appendix E contains additional information regarding small-strain shear stiffness parameters.

Section 2.2 contains discretized profiles for use in the ground response software, Strata. Profiles were generated at each boring location where liquefaction or cyclic softening potential was identified.

Section 2.3 contains peak acceleration calculations for use in the liquefaction and cyclic softening triggering analysis.

Section 3 contains information supporting the liquefaction and cyclic softening analysis. Section 3.1 contains laboratory-based sand-like/clay-like determinations for each material with the necessary data.

Section 3.2 contains information supporting static shear stress ratio calculations. Section 3.2.1 contains graphical outputs with contours of vertical effective stress and XY-shear stress at the analyzed cross-section. Calculations of static shear stress ratio for each boring/sounding analyzed in the liquefaction triggering analysis is located in Section 3.2.2.

Section 3.3 contains outputs from the SPT-based liquefaction assessment for both design earthquakes considered.

Section 3.4 contains outputs from the CPT-based liquefaction assessment. Included in these outputs are plots showing soil behavior type according to Robertson (2008).

Section 3.5 contains several figures illustrated the results of the liquefaction and cyclic softening analyses. These figures show liquefaction triggering and clay-like/sand-like determination results. Plan views are presented for each applicable soil horizon. Cross-section views are also presented for the full boring/sounding.

Section 3.6 contains samples of SPT and CPT-based liquefaction triggering calculations.

Section 4 contains details calculations supporting the liquefied residual strength derivations for the Fly Ash and Subunit 3.
