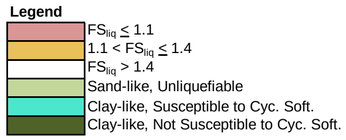
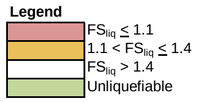
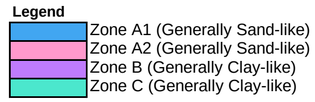
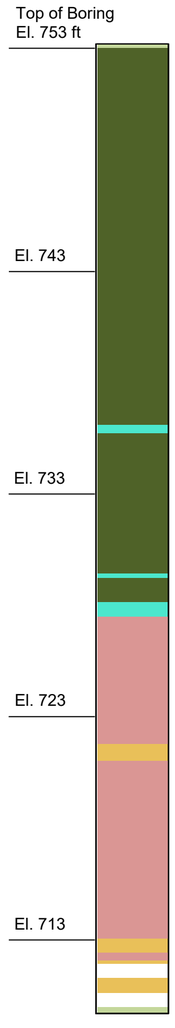
Adapted from "Discussion of 'Liquefaction Potential of Silts from CPTu'" (Robertson 2008). Zone A_1 and Zone A_2 samples are generally sand-like. Zone B samples are generally clay-like and not susceptible to cyclic softening. Zone C samples are generally clay-like and susceptible to cyclic softening. Note that the transition from clay-like to sand-like in this chart does not exactly match the liquefaction calculations herein; that is, some transitional samples in Zone B and Zone C will be treated as sand-like and analyzed for liquefaction if the calculations indicate as such.



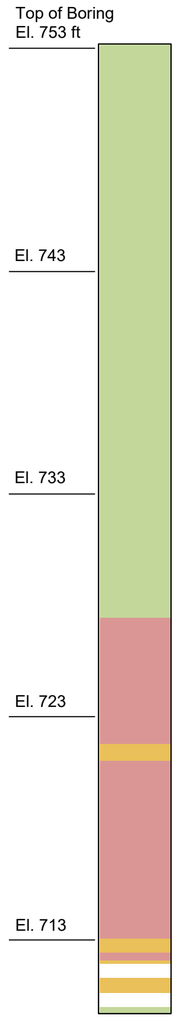




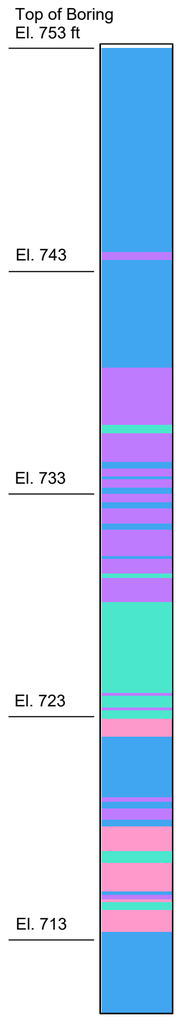
CPT-04A, Liquefaction Triggering Results



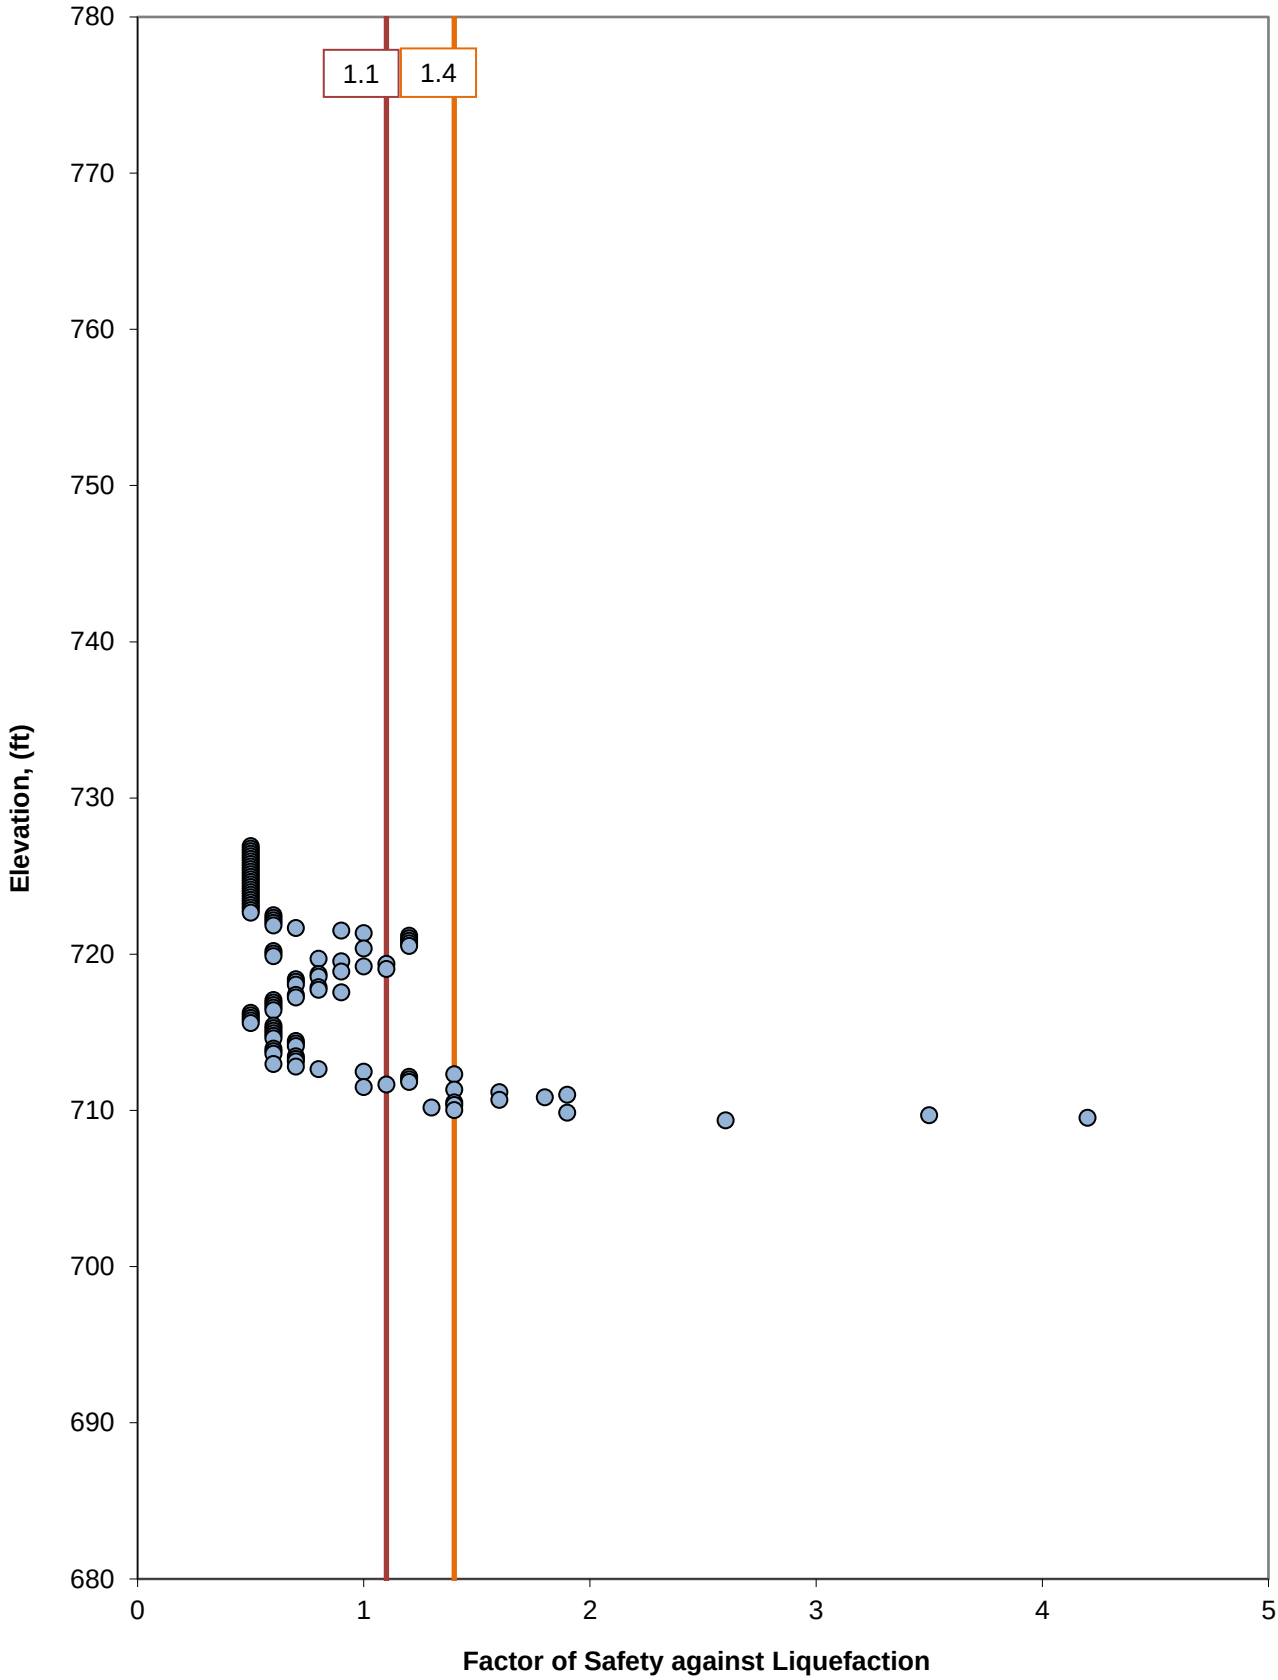
CPT-04A, Liquefaction Triggering Results



CPT-04A, Robertson Soil Type



KIF TDEC Stability, Boring = CPT-04A, Source = 10 Hz, Mw = 6, Event = Design EQ, CPT Data, Simplified Stress-Based Approach



Inputs

Project Information

Stantec Project Number =	175668043
Project Name =	KIF TDEC Stability
CPT ID =	CPT-05A

Boring Location (optional)

Northing =	
Easting =	
OR	
Baseline Station =	
Offset (+ Right) =	

Using qt (corrected for u2 PWP) or qc (backcalculated uncorrected field tip)

Cone ID (optional) =	AD184	
Use qc instead of qt?	0	(1: Yes, 0: No)
Cone Area Ratio (a) =	0.80	

Drilling Information

Top of Hole Elevation =	754.0	feet
Water Depth during CPT (negative for U/S borings) =	2.5	feet
Depth data collection began =	0.16	feet
Avg. Total Unit Wt. Above 1st Sample =	120.00	pcf

During Earthquake Information

Water Depth during EQ (relative to CPT TOH, negative for U/S borings) =	5.0	feet
Final Grade Elevation during EQ =	753.0	feet
Avg. Total Unit Wt. of Cut/Fill =	120	pcf

Nonlinear Pore Water Pressure Profile

Custom Pore Water Pressure Profile?	0	(1: Yes, 0: No)

If previous answer is No, hydrostatic pressures are assumed.

α Curve Fit Parameters

Associated α profile:	ng_Pond_Section, KIF-BF-SPT3_NOR	
α at each Sample Depth known?	1	(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (α vs. depth curve)

If defaulting to K_α=1 (i.e., level ground), assign values of zero to all curve fit parameters below to make alpha zero and thus, K_α will be one.

m0:	

Associated ground response profile:	shing_Pond_Section, KIF-BF-SPT3	
Get CSR from shear stress envelope?	0	(1: Yes, 0: No)

If previous answer is No, then CSR will be calculated using a_{max} and r_d

Max. Shear Stress at each sample depth known?		(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (shear stress vs. depth curve)

Max. Shear Stress Curve Fit Parameters (from ground response analysis)

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Facility: KIF TDEC Stability
Project No.: 175668043
CPT ID: CPT-05A

Water Elevation during CPT:	751.5	ft
Depth to Water during CPT:	2.5	ft *(relative to ground surface during CPT)*
Water Elevation during Earthquake:	749.0	ft
Depth to Water during Earthquake:	5.0	ft *(relative to ground surface during CPT)*
Final Grade Elevation during EQ:	753	ft *(if no fill, then set this equal to top of CPT hole elev.)*
Height of Final Grade above CPT TOH:	-1.0	ft *(relative to ground surface during CPT, + Fill, - Cut)*
Unit Weight of Cut/Fill to Achieve Final Grade	120	pcf
Cut/Fill Total Stress (+ Fill, - Cut):	-0.06	tsf

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Project Site: **KIF TDEC Stability**
Stantec Project No.: **175668043**
CPT ID: **CPT-05A**

Depth to Water during Earthquake:	5.0	ft
Final Grade Elevation during EQ:	753.0	ft
Height of Final Grade above CPT TOH:	-1.0	ft
Normalize K_σ to:	1.058	tsf
a_{max} at top of ground surface:	0.21	g
Earthquake Magnitude:	6.00	M_W
Earthquake File or Source Zone:	10	Hz

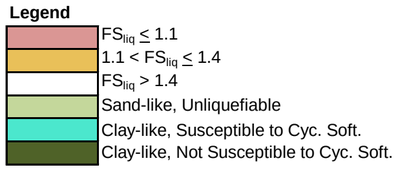
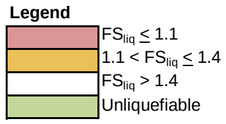
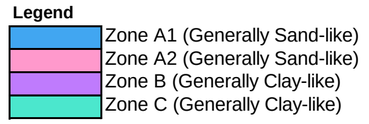
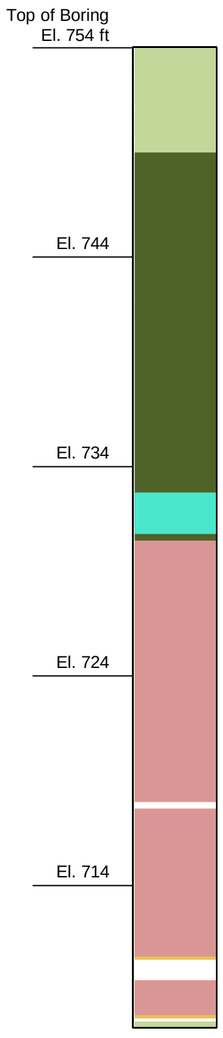
Adapted from "Discussion of 'Liquefaction Potential of Silts from CPTu'" (Robertson 2008). Zone A_1 and Zone A_2 samples are generally sand-like. Zone B samples are generally clay-like and not susceptible to cyclic softening. Zone C samples are generally clay-like and susceptible to cyclic softening. Note that the transition from clay-like to sand-like in this chart does not exactly match the liquefaction calculations herein; that is, some transitional samples in Zone B and Zone C will be treated as sand-like and analyzed for liquefaction if the calculations indicate as such.



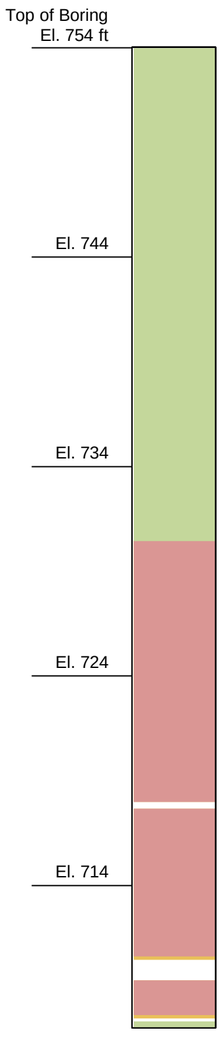




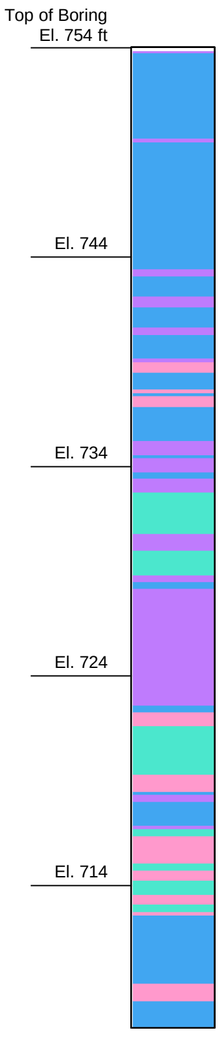
CPT-05A, Liquefaction Triggering Results



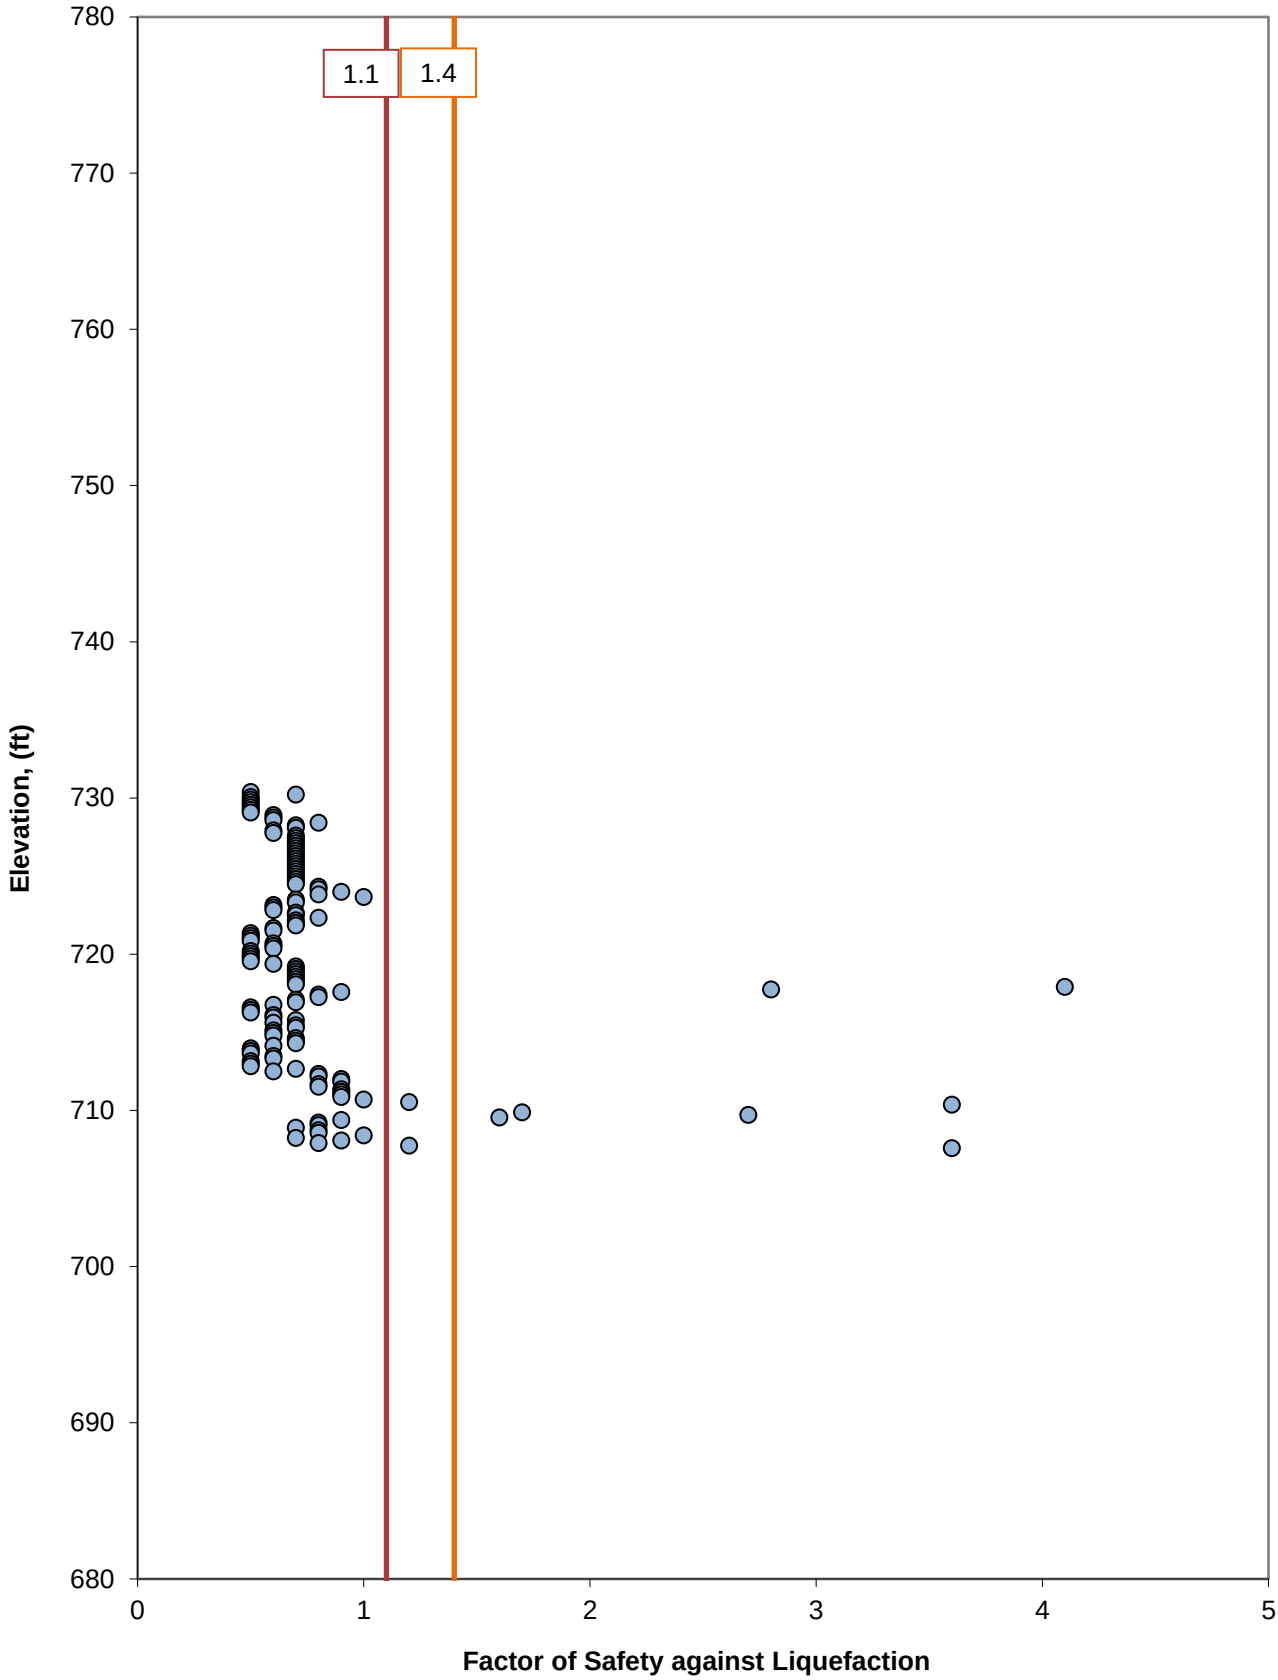
CPT-05A, Liquefaction Triggering Results



CPT-05A, Robertson Soil Type



KIF TDEC Stability, Boring = CPT-05A, Source = 10 Hz, Mw = 6, Event = Design EQ, CPT Data, Simplified Stress-Based Approach



Project Information

Stantec Project Number =	175668043
Project Name =	KIF TDEC Stability
CPT ID =	CPT-07

Boring Location (optional)

Northing =	
Easting =	

OR

Baseline Station =	
Offset (+ Right) =	

Using qt (corrected for u2 PWP) or qc (backcalculated uncorrected field tip)

Cone ID (optional) =	AD184	
Use qc instead of qt?	0	(1: Yes, 0: No)
Cone Area Ratio (a) =	0.80	

Drilling Information

Top of Hole Elevation =	754.0	feet
Water Depth during CPT (negative for U/S borings) =	6.0	feet
Depth data collection began =	0.16	feet
Avg. Total Unit Wt. Above 1st Sample =	120.00	pcf

During Earthquake Information

Water Depth during EQ (relative to CPT TOH, negative for U/S borings) =	5.0	feet
Final Grade Elevation during EQ =	753.0	feet
Avg. Total Unit Wt. of Cut/Fill =	120	pcf

Nonlinear Pore Water Pressure Profile

Custom Pore Water Pressure Profile?	0	(1: Yes, 0: No)

If previous answer is No, hydrostatic pressures are assumed.

α Curve Fit Parameters

Associated α profile:	ng_Pond_Section, KIF-BF-SPT3_NOR	
α at each Sample Depth known?	1	(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (α vs. depth curve)

If defaulting to K_α=1 (i.e., level ground), assign values of zero to all curve fit parameters below to make alpha zero and thus, K_α will be one.

m4:	
m3:	
m2:	
m1:	
m0:	

Associated ground response profile:	shing_Pond_Section, KIF-BF-SPT3	
Get CSR from shear stress envelope?	0	(1: Yes, 0: No)

If previous answer is No, then CSR will be calculated using a_{max} and r_d

Max. Shear Stress at each sample depth known?		(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (shear stress vs. depth curve)

Max. Shear Stress Curve Fit Parameters (from ground response analysis)

m4:	
m3:	
m2:	
m1:	

Earthquake Information

EQ Source (e.g., New Madrid)	10 Hz
Event (e.g., MCE, OBE)	Design EQ
a_{max} (g) (top of ground surface)	0.21
EQ Mag (Mw)	6.0

Inputs

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Project Site: **KIF TDEC Stability**
Stantec Project No.: **175668043**
CPT ID: **CPT-07**

Depth to Water during Earthquake:	5.0	ft
Final Grade Elevation during EQ:	753.0	ft
Height of Final Grade above CPT TOH:	-1.0	ft
Normalize K_σ to:	1.058	tsf
a_{max} at top of ground surface:	0.21	g
Earthquake Magnitude:	6.00	M_W
Earthquake File or Source Zone:	10	Hz

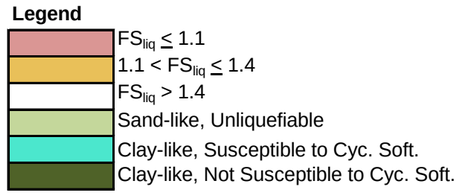
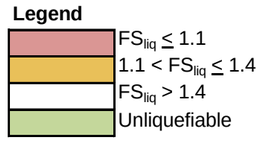
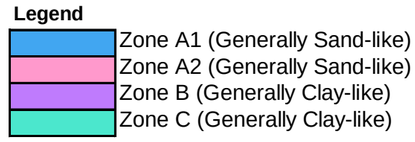
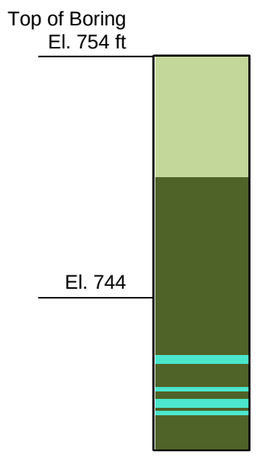
Adapted from "Discussion of 'Liquefaction Potential of Silts from CPTu'" (Robertson 2008). Zone A_1 and Zone A_2 samples are generally sand-like. Zone B samples are generally clay-like and not susceptible to cyclic softening. Zone C samples are generally clay-like and susceptible to cyclic softening. Note that the transition from clay-like to sand-like in this chart does not exactly match the liquefaction calculations herein; that is, some transitional samples in Zone B and Zone C will be treated as sand-like and analyzed for liquefaction if the calculations indicate as such.



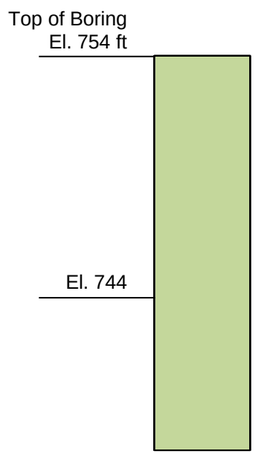




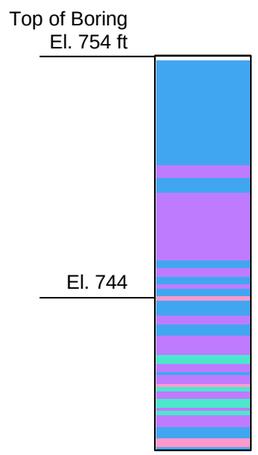
CPT-07, Liquefaction Triggering Results



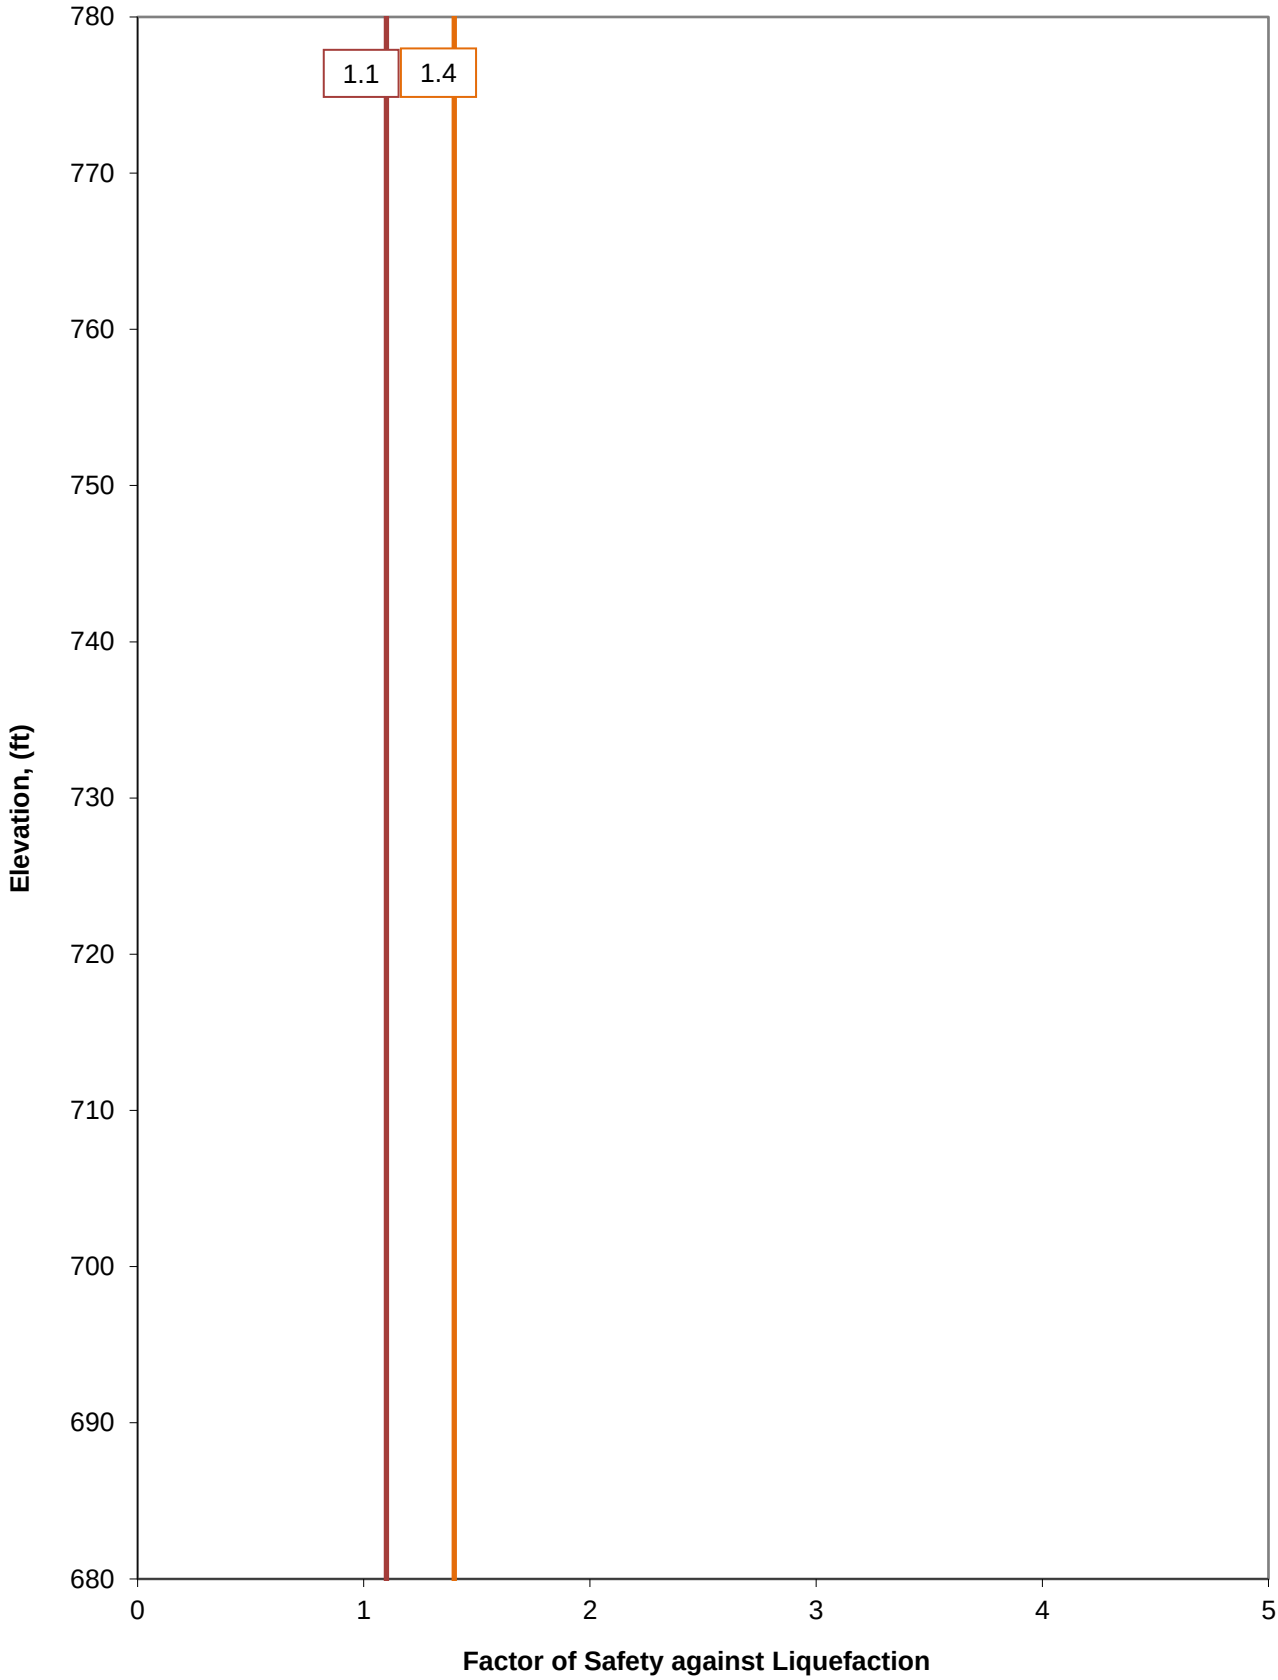
CPT-07, Liquefaction Triggering Results



CPT-07, Robertson Soil Type



KIF TDEC Stability, Boring = CPT-07, Source = 10 Hz, Mw = 6, Event = Design EQ, CPT Data, Simplified Stress-Based Approach



Project Information

Stantec Project Number =	175668043
Project Name =	KIF TDEC Stability
CPT ID =	KIF-BF-CPT-2

Boring Location (optional)

Northing =	
Easting =	

OR

Baseline Station =	
Offset (+ Right) =	

Using qt (corrected for u2 PWP) or qc (backcalculated uncorrected field tip)

Cone ID (optional) =	AD184	
Use qc instead of qt?	0	(1: Yes, 0: No)
Cone Area Ratio (a) =	0.80	

Drilling Information

Top of Hole Elevation =	769.0	feet
Water Depth during CPT (negative for U/S borings) =	14.0	feet
Depth data collection began =	0.16	feet
Avg. Total Unit Wt. Above 1st Sample =	122.00	pcf

During Earthquake Information

Water Depth during EQ (relative to CPT TOH, negative for U/S borings) =	15.0	feet
Final Grade Elevation during EQ =	769.0	feet
Avg. Total Unit Wt. of Cut/Fill =	122	pcf

Nonlinear Pore Water Pressure Profile

Custom Pore Water Pressure Profile?	0	(1: Yes, 0: No)

If previous answer is No, hydrostatic pressures are assumed.

α Curve Fit Parameters

Associated α profile:	ng_Pond_Section, KIF-BF-CPT2_NOR	
α at each Sample Depth known?	1	(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (α vs. depth curve)

If defaulting to K_α=1 (i.e., level ground), assign values of zero to all curve fit parameters below to make alpha zero and thus, K_σ will be one.

m4:	
m3:	
m2:	
m1:	
m0:	

Associated ground response profile:	shing_Pond_Section, KIF-BF-SPT5	
Get CSR from shear stress envelope?	0	(1: Yes, 0: No)

If previous answer is No, then CSR will be calculated using a_{max} and r_d

Max. Shear Stress at each sample depth known?		(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (shear stress vs. depth curve)

Max. Shear Stress Curve Fit Parameters (from ground response analysis)

m4:	
m3:	
m2:	
m1:	

Earthquake Information

EQ Source (e.g., New Madrid)	10 Hz
Event (e.g., MCE, OBE)	Design EQ
a_{max} (g) (top of ground surface)	0.19
EQ Mag (Mw)	6.0

Inputs

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Facility: KIF TDEC Stability
Project No.: 175668043
CPT ID: KIF-BF-CPT-2

Water Elevation during CPT:	755.0	ft
Depth to Water during CPT:	14.0	ft *(relative to ground surface during CPT)*
Water Elevation during Earthquake:	754.0	ft
Depth to Water during Earthquake:	15.0	ft *(relative to ground surface during CPT)*
Final Grade Elevation during EQ:	769	ft *(if no fill, then set this equal to top of CPT hole elev.)*
Height of Final Grade above CPT TOH:	0.0	ft *(relative to ground surface during CPT, + Fill, - Cut)*
Unit Weight of Cut/Fill to Achieve Final Grade	122	pcf
Cut/Fill Total Stress (+ Fill, - Cut):	0.00	tsf

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Project Site: KIF TDEC Stability
Project No.: 175668043
CPT ID: KIF-BF-CPT-2

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Project Site: KIF TDEC Stability
Stantec Project No.: 175668043
CPT ID: KIF-BF-CPT-2

Depth to Water during Earthquake:	15.0	ft
Final Grade Elevation during EQ:	769.0	ft
Height of Final Grade above CPT TOH:	0.0	ft
Normalize K_σ to:	1.058	tsf
a_{max} at top of ground surface:	0.19	g
Earthquake Magnitude:	6.00	M_W
Earthquake File or Source Zone:	10	Hz

Shear Stress Fit Parameters

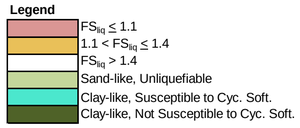
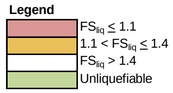
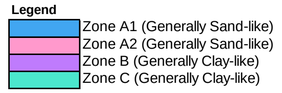
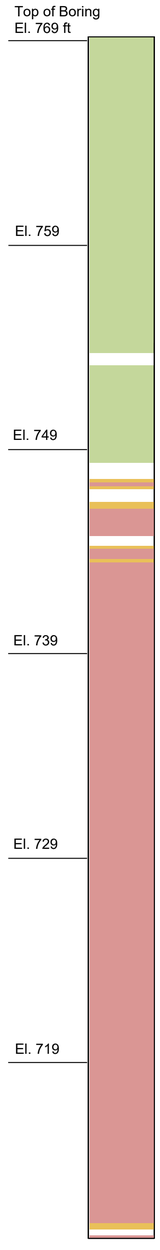
Adapted from "Discussion of 'Liquefaction Potential of Silts from CPTu'" (Robertson 2008). Zone A_1 and Zone A_2 samples are generally sand-like. Zone B samples are generally clay-like and not susceptible to cyclic softening. Zone C samples are generally clay-like and susceptible to cyclic softening. Note that the transition from clay-like to sand-like in this chart does not exactly match the liquefaction calculations herein; that is, some transitional samples in Zone B and Zone C will be treated as sand-like and analyzed for liquefaction if the calculations indicate as such.



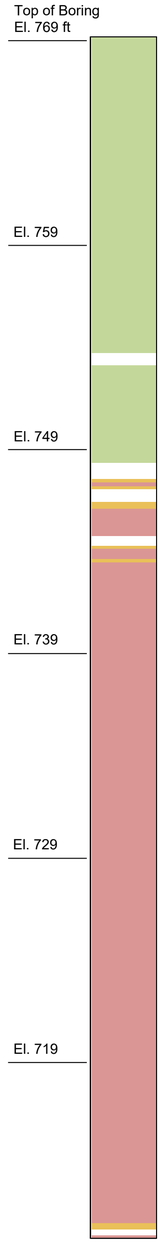




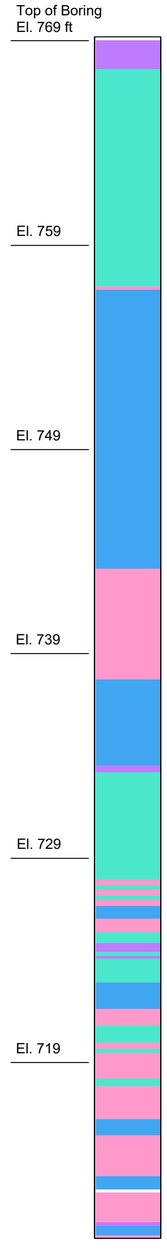
KIF-BF-CPT-2, Liquefaction Triggering Results



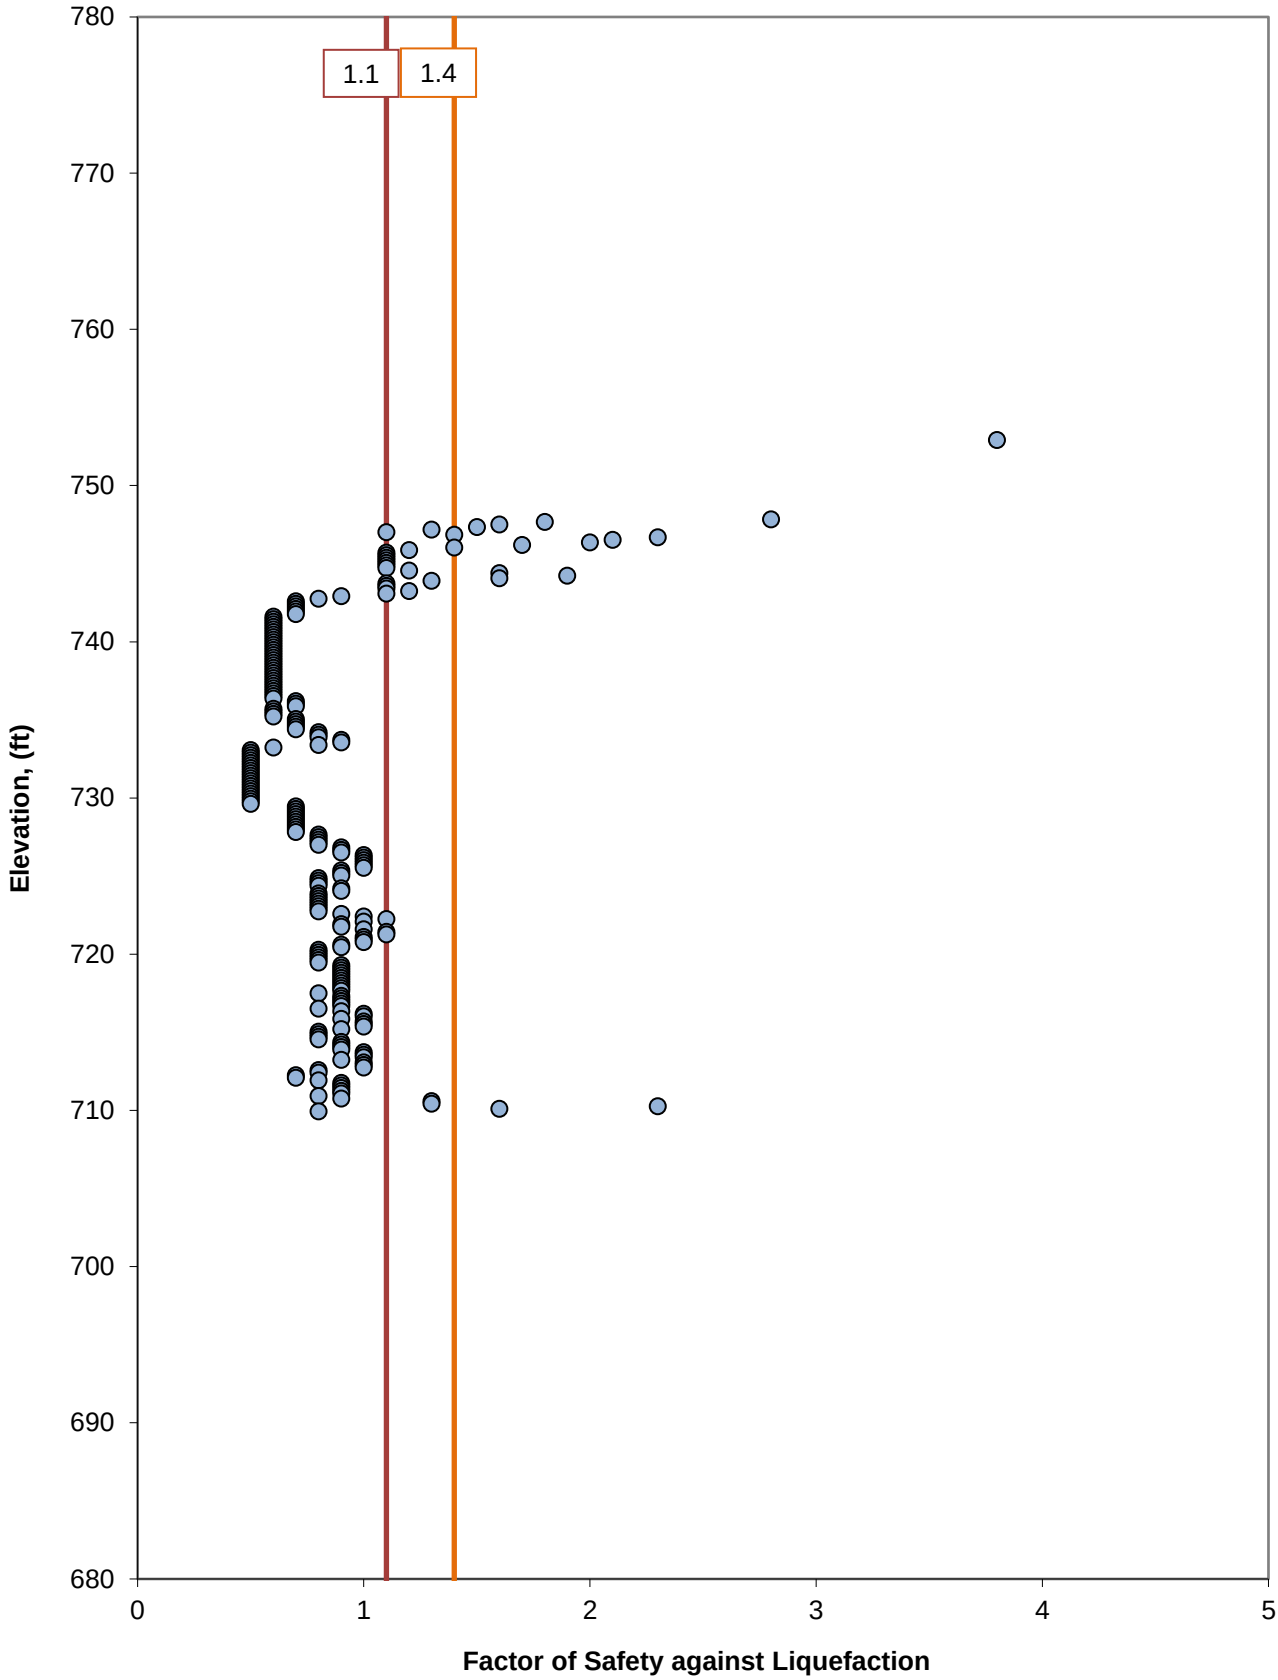
KIF-BF-CPT-2, Liquefaction Triggering Results



KIF-BF-CPT-2, Robertson Soil Type



KIF TDEC Stability, Boring = KIF-BF-CPT-2, Source = 10 Hz, Mw = 6, Event = Design EQ,
CPT Data, Simplified Stress-Based Approach



Project Information

Stantec Project Number =	175668043
Project Name =	KIF TDEC Stability
CPT ID =	KIF-BF-CPT-3A

Boring Location (optional)

Northing =	
Easting =	

OR

Baseline Station =	
Offset (+ Right) =	

Using qt (corrected for u2 PWP) or qc (backcalculated uncorrected field tip)

Cone ID (optional) =	AD184	
Use qc instead of qt?	0	(1: Yes, 0: No)
Cone Area Ratio (a) =	0.80	

Drilling Information

Top of Hole Elevation =	748.0	feet
Water Depth during CPT (negative for U/S borings) =	9.0	feet
Depth data collection began =	0.16	feet
Avg. Total Unit Wt. Above 1st Sample =	120.00	pcf

During Earthquake Information

Water Depth during EQ (relative to CPT TOH, negative for U/S borings) =	6.5	feet
Final Grade Elevation during EQ =	748.0	feet
Avg. Total Unit Wt. of Cut/Fill =		pcf

Nonlinear Pore Water Pressure Profile

Custom Pore Water Pressure Profile?	0	(1: Yes, 0: No)

If previous answer is No, hydrostatic pressures are assumed.

α Curve Fit Parameters

Associated α profile:	g_Pond_Section, KIF-BF-CPT3A_NOR	
α at each Sample Depth known?	1	(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (α vs. depth curve)

If defaulting to K_α=1 (i.e., level ground), assign values of zero to all curve fit parameters below to make alpha zero and thus, K_α will be one.

m4:	
m3:	
m2:	
m1:	
m0:	

Associated ground response profile:	shing_Pond_Section, KIF-BF-SPT3	
Get CSR from shear stress envelope?	0	(1: Yes, 0: No)

If previous answer is No, then CSR will be calculated using a_{max} and r_d

Max. Shear Stress at each sample depth known?		(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (shear stress vs. depth curve)

Max. Shear Stress Curve Fit Parameters (from ground response analysis)

m4:	
m3:	
m2:	
m1:	

Earthquake Information

EQ Source (e.g., New Madrid)	10 Hz
Event (e.g., MCE, OBE)	Design EQ
a_{max} (g) (top of ground surface)	0.21
EQ Mag (Mw)	6.0

Inputs

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Facility: KIF TDEC Stability
Project No.: 175668043
CPT ID: KIF-BF-CPT-3A

Water Elevation during CPT:	739.0	ft
Depth to Water during CPT:	9.0	ft *(relative to ground surface during CPT)*
Water Elevation during Earthquake:	741.5	ft
Depth to Water during Earthquake:	6.5	ft *(relative to ground surface during CPT)*
Final Grade Elevation during EQ:	748	ft *(if no fill, then set this equal to top of CPT hole elev.)*
Height of Final Grade above CPT TOH:	0.0	ft *(relative to ground surface during CPT, + Fill, - Cut)*
Unit Weight of Cut/Fill to Achieve Final Grade	0	pcf
Cut/Fill Total Stress (+ Fill, - Cut):	0.00	tsf

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Project Site: KIF TDEC Stability
Project No.: 175668043
CPT ID: KIF-BF-CPT-3A

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Project Site: KIF TDEC Stability
Stantec Project No.: 175668043
CPT ID: KIF-BF-CPT-3A

Depth to Water during Earthquake:	6.5	ft
Final Grade Elevation during EQ:	748.0	ft
Height of Final Grade above CPT TOH:	0.0	ft
Normalize K_σ to:	1.058	tsf
a_{max} at top of ground surface:	0.21	g
Earthquake Magnitude:	6.00	M_W
Earthquake File or Source Zone:	10	Hz

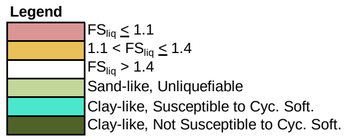
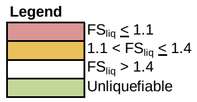
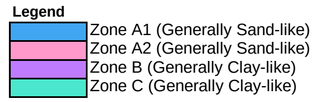
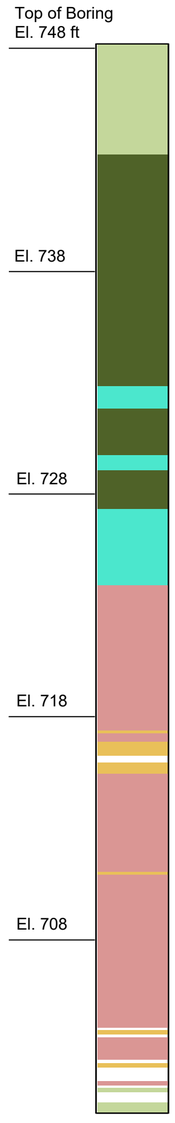
Adapted from "Discussion of 'Liquefaction Potential of Silts from CPTu'" (Robertson 2008). Zone A_1 and Zone A_2 samples are generally sand-like. Zone B samples are generally clay-like and not susceptible to cyclic softening. Zone C samples are generally clay-like and susceptible to cyclic softening. Note that the transition from clay-like to sand-like in this chart does not exactly match the liquefaction calculations herein; that is, some transitional samples in Zone B and Zone C will be treated as sand-like and analyzed for liquefaction if the calculations indicate as such.



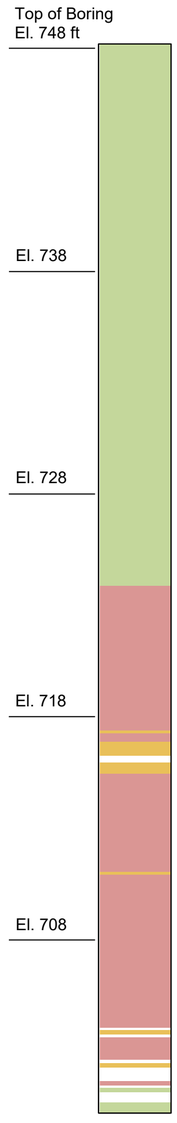




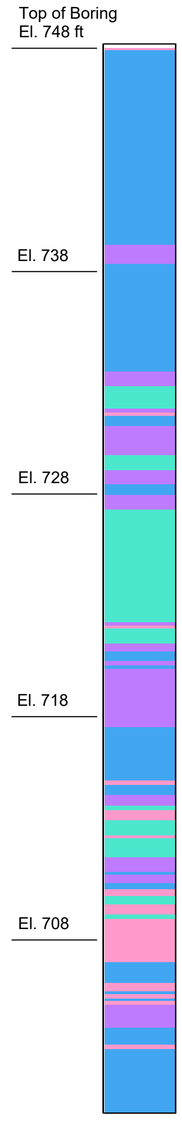
KIF-BF-CPT-3A, Liquefaction Triggering Results



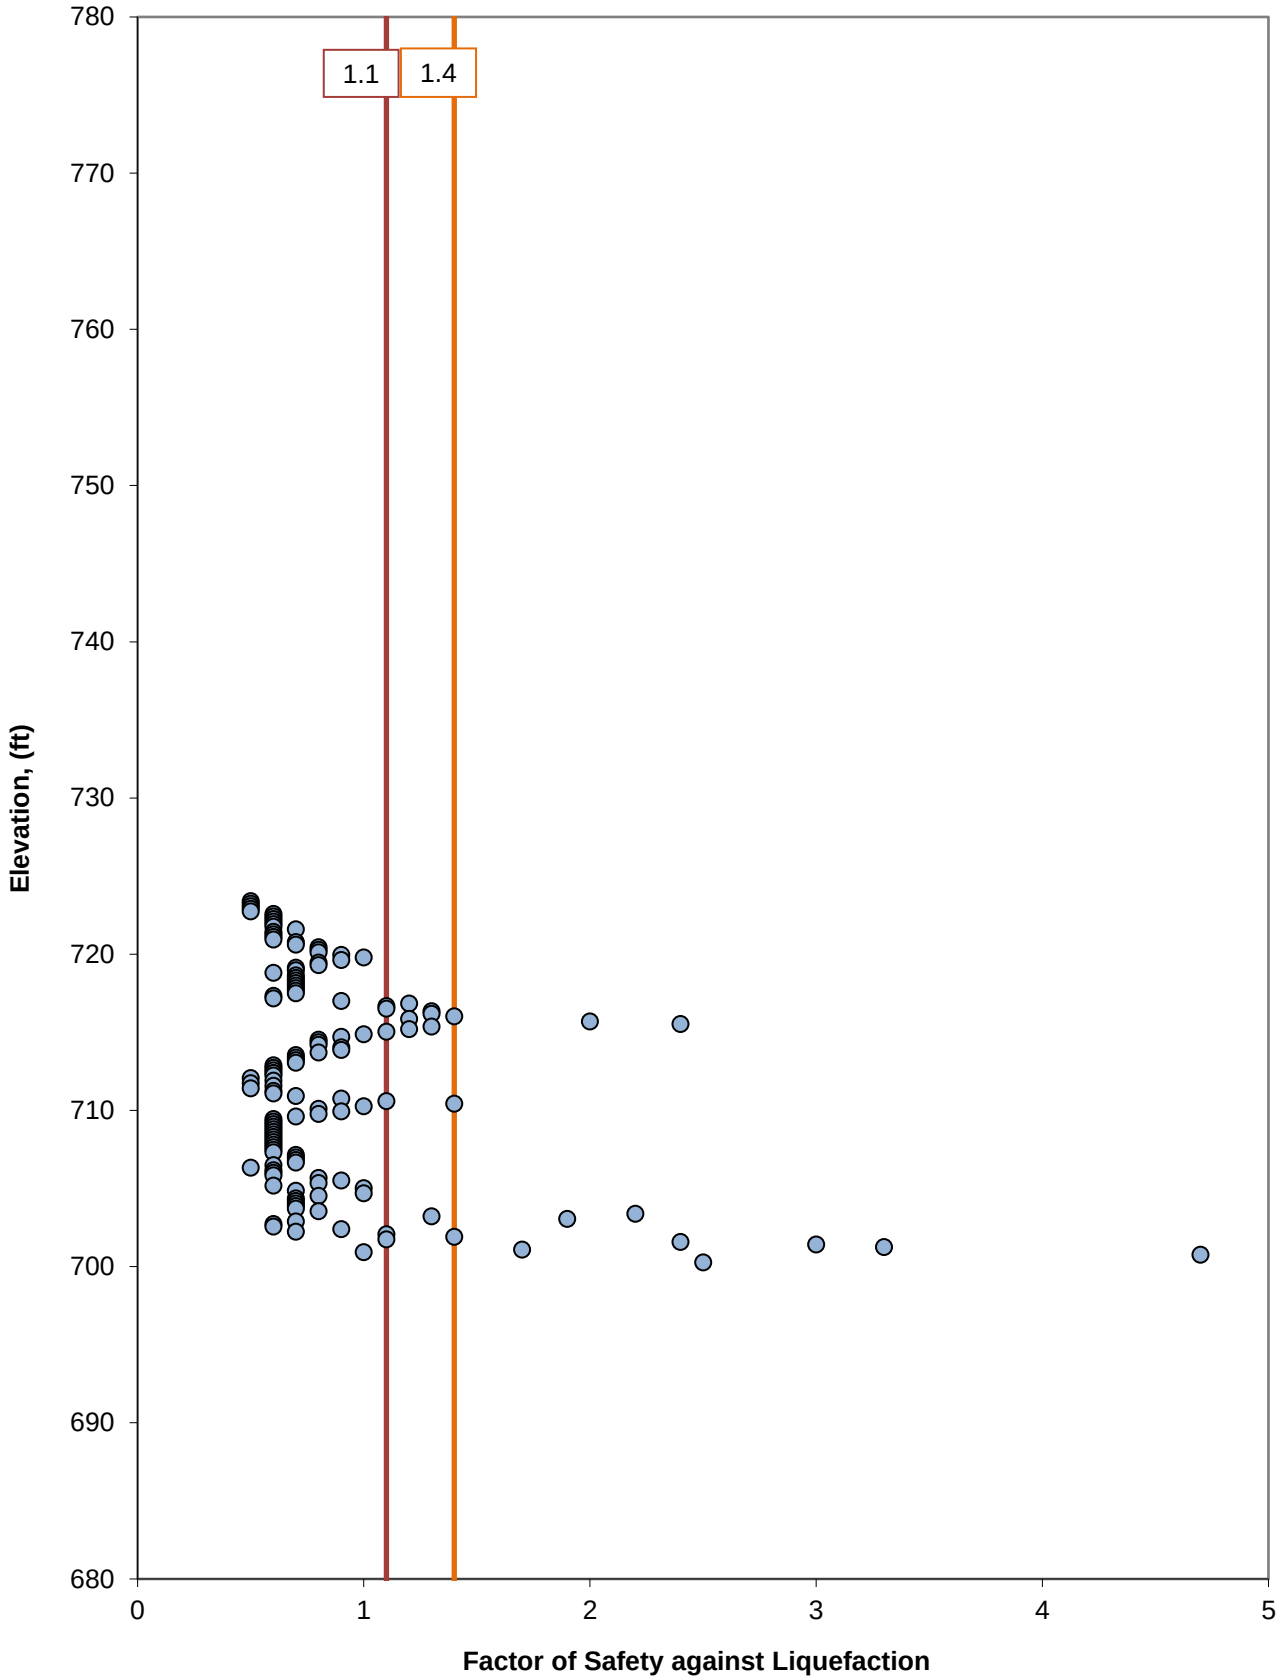
KIF-BF-CPT-3A, Liquefaction Triggering Results



KIF-BF-CPT-3A, Robertson Soil Type



KIF TDEC Stability, Boring = KIF-BF-CPT-3A, Source = 10 Hz, Mw = 6, Event = Design EQ, CPT Data, Simplified Stress-Based Approach



Project Information

Stantec Project Number =	175668043
Project Name =	KIF TDEC Stability
CPT ID =	KIF-BF-CPT-4AA

Boring Location (optional)

Northing =	
Easting =	

OR

Baseline Station =	
Offset (+ Right) =	

Using qt (corrected for u2 PWP) or qc (backcalculated uncorrected field tip)

Cone ID (optional) =	AD184	
Use qc instead of qt?	0	(1: Yes, 0: No)
Cone Area Ratio (a) =	0.80	

Drilling Information

Top of Hole Elevation =	769.0	feet
Water Depth during CPT (negative for U/S borings) =	10.0	feet
Depth data collection began =	0.16	feet
Avg. Total Unit Wt. Above 1st Sample =	120.00	pcf

During Earthquake Information

Water Depth during EQ (relative to CPT TOH, negative for U/S borings) =	6.5	feet
Final Grade Elevation during EQ =	769.0	feet
Avg. Total Unit Wt. of Cut/Fill =	120	pcf

Nonlinear Pore Water Pressure Profile

Custom Pore Water Pressure Profile?	0	(1: Yes, 0: No)

If previous answer is No, hydrostatic pressures are assumed.

α Curve Fit Parameters

Associated α profile:	ng_Pond_Section, KIF-BF-SPT5_NOR	
α at each Sample Depth known?	1	(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (α vs. depth curve)

If defaulting to K_α=1 (i.e., level ground), assign values of zero to all curve fit parameters below to make alpha zero and thus, K_α will be one.

m4:	
m3:	
m2:	
m1:	
m0:	

Associated ground response profile:	hing_Pond_Section, KIF-BF-CPT4AA	
Get CSR from shear stress envelope?	0	(1: Yes, 0: No)

If previous answer is No, then CSR will be calculated using a_{max} and r_d

Max. Shear Stress at each sample depth known?		(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (shear stress vs. depth curve)

Max. Shear Stress Curve Fit Parameters (from ground response analysis)

m4:	
m3:	
m2:	
m1:	

Earthquake Information

EQ Source (e.g., New Madrid)	10 Hz
Event (e.g., MCE, OBE)	Design EQ
a_{max} (g) (top of ground surface)	0.20
EQ Mag (Mw)	6.0

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Facility: KIF TDEC Stability
Project No.: 175668043
CPT ID: KIF-BF-CPT-4AA

Water Elevation during CPT:	759.0	ft
Depth to Water during CPT:	10.0	ft *(relative to ground surface during CPT)*
Water Elevation during Earthquake:	762.5	ft
Depth to Water during Earthquake:	6.5	ft *(relative to ground surface during CPT)*
Final Grade Elevation during EQ:	769	ft *(if no fill, then set this equal to top of CPT hole elev.)*
Height of Final Grade above CPT TOH:	0.0	ft *(relative to ground surface during CPT, + Fill, - Cut)*
Unit Weight of Cut/Fill to Achieve Final Grade	120	pcf
Cut/Fill Total Stress (+ Fill, - Cut):	0.00	tsf

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Project Site: KIF TDEC Stability
Project No.: 175668043
CPT ID: KIF-BF-CPT-4AA

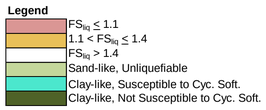
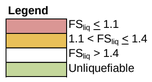
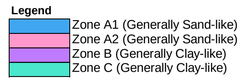
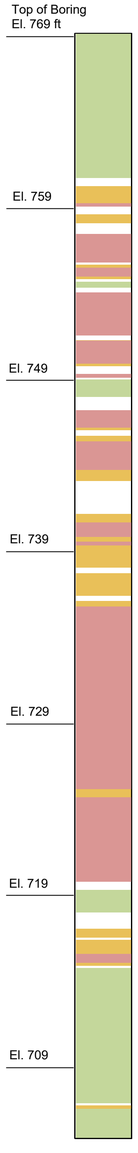
Adapted from "Discussion of 'Liquefaction Potential of Silts from CPTu'" (Robertson 2008). Zone A_1 and Zone A_2 samples are generally sand-like. Zone B samples are generally clay-like and not susceptible to cyclic softening. Zone C samples are generally clay-like and susceptible to cyclic softening. Note that the transition from clay-like to sand-like in this chart does not exactly match the liquefaction calculations herein; that is, some transitional samples in Zone B and Zone C will be treated as sand-like and analyzed for liquefaction if the calculations indicate as such.



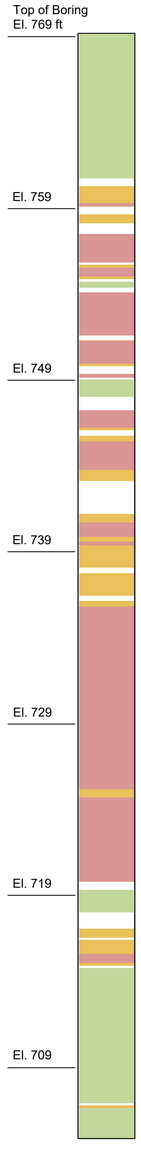




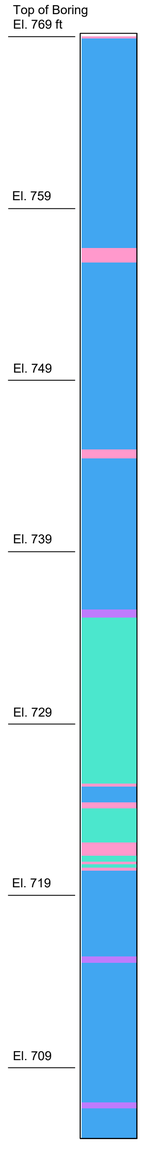
KIF-BF-CPT-4AA, Liquefaction Triggering Results



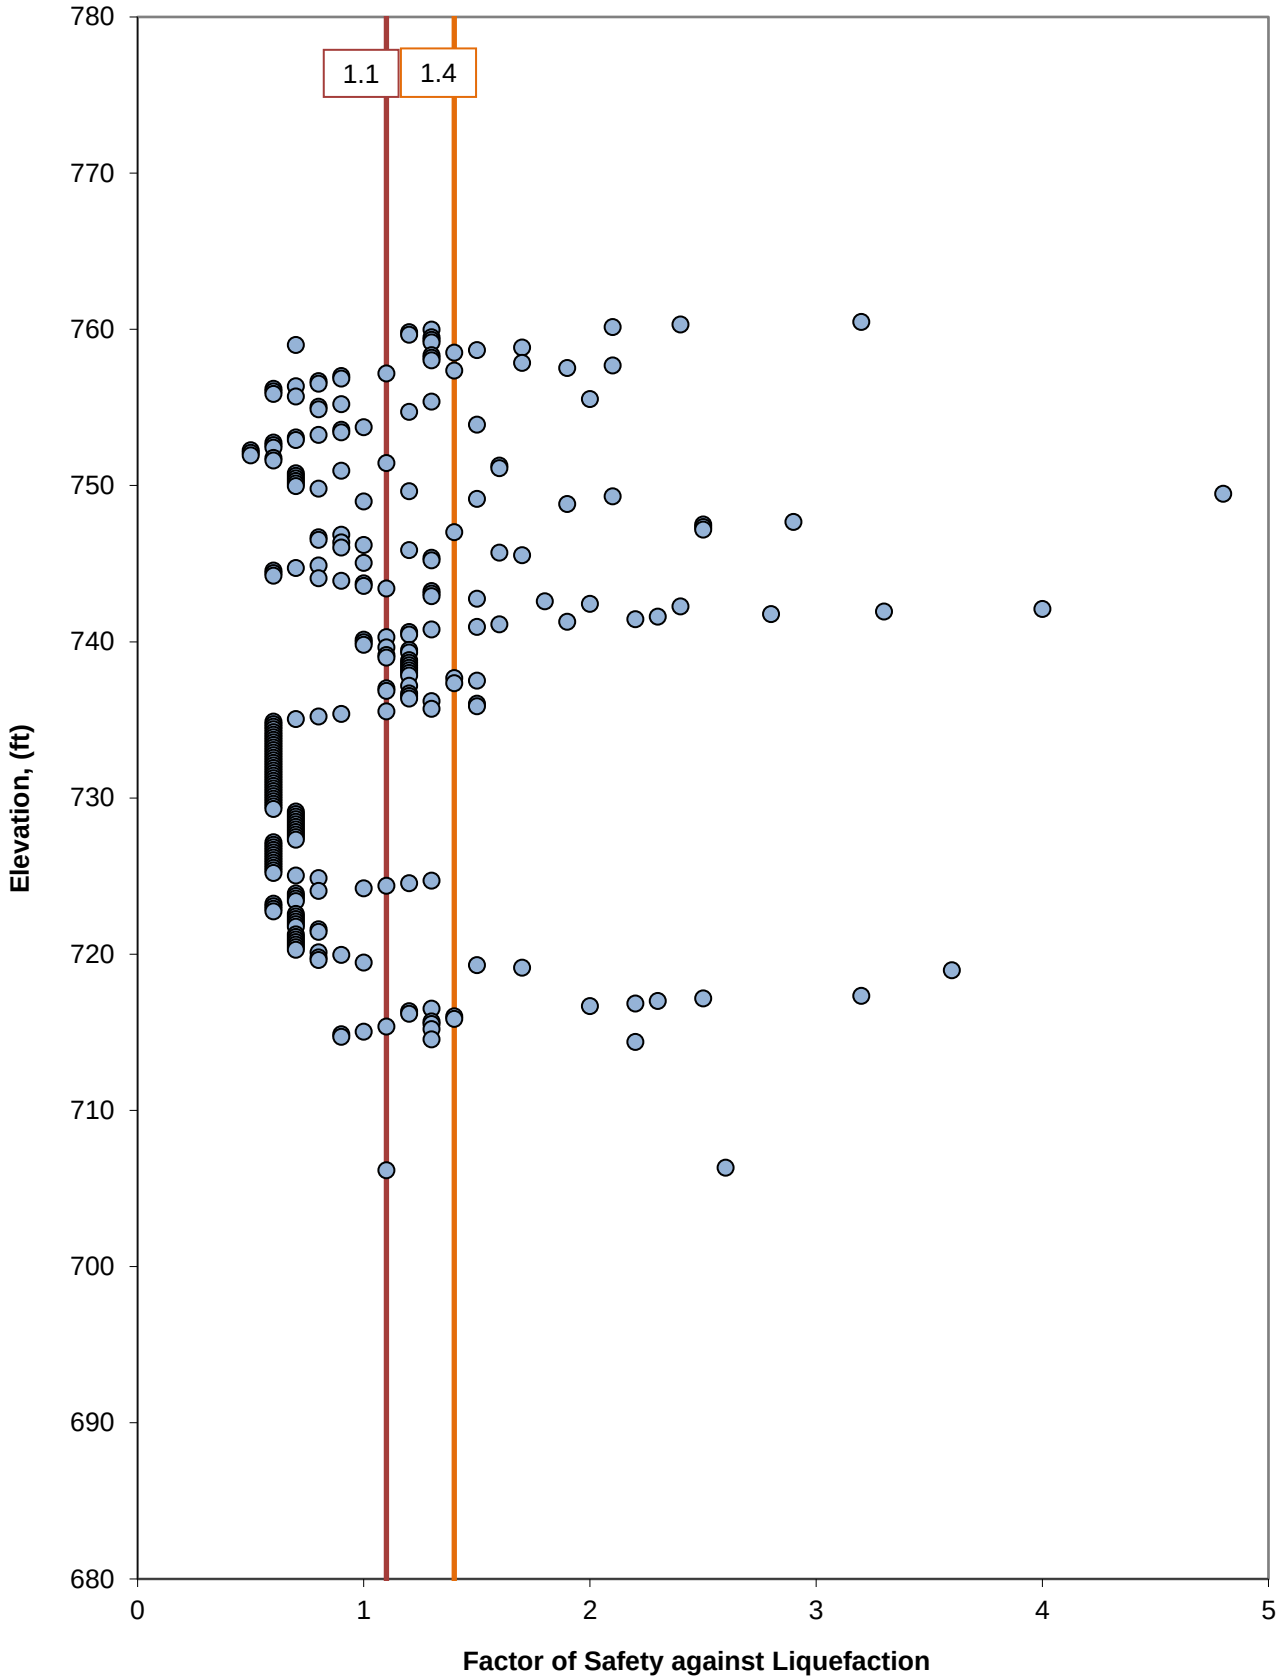
KIF-BF-CPT-4AA, Liquefaction Triggering Results



KIF-BF-CPT-4AA, Robertson Soil Type



KIF TDEC Stability, Boring = KIF-BF-CPT-4AA, Source = 10 Hz, Mw = 6, Event = Design EQ, CPT Data, Simplified Stress-Based Approach



Inputs

Project Information

Stantec Project Number =	175668043
Project Name =	KIF TDEC Stability
CPT ID =	KIF-BF-CPT-5B

Boring Location (optional)

Northing =	
Easting =	
OR	
Baseline Station =	
Offset (+ Right) =	

Using qt (corrected for u2 PWP) or qc (backcalculated uncorrected field tip)

Cone ID (optional) =	AD184	
Use qc instead of qt?	0	(1: Yes, 0: No)
Cone Area Ratio (a) =	0.80	

Drilling Information

Top of Hole Elevation =	769.0	feet
Water Depth during CPT (negative for U/S borings) =	13.0	feet
Depth data collection began =	0.16	feet
Avg. Total Unit Wt. Above 1st Sample =	122.00	pcf

During Earthquake Information

Water Depth during EQ (relative to CPT TOH, negative for U/S borings) =	15.0	feet
Final Grade Elevation during EQ =	766.0	feet
Avg. Total Unit Wt. of Cut/Fill =	122	pcf

Nonlinear Pore Water Pressure Profile

Custom Pore Water Pressure Profile?	0	(1: Yes, 0: No)

If previous answer is No, hydrostatic pressures are assumed.

α Curve Fit Parameters

Associated α profile:	g_Pond_Section, KIF-BF-CPT5B_NOR	
α at each Sample Depth known?	1	(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (α vs. depth curve)
If defaulting to K_α=1 (i.e., level ground), assign values of zero to all curve fit parameters below to make alpha zero and thus, K_α will be one.

m4:	
m3:	
m2:	
m1:	
m0:	

Associated ground response profile:	shing_Pond_Section, KIF-BF-SPT5	
Get CSR from shear stress envelope?	0	(1: Yes, 0: No)

If previous answer is No, then CSR will be calculated using a_{max} and r_d

Max. Shear Stress at each sample depth known?		(1: Yes, 0: No)

If previous answer is No, then enter curve fit parameters below (shear stress vs. depth curve)

Max. Shear Stress Curve Fit Parameters (from ground response analysis)

m4:	
m3:	
m2:	
m1:	

Earthquake Information

EQ Source (e.g., New Madrid)	10 Hz
Event (e.g., MCE, OBE)	Design EQ
a_{max} (g) (top of ground surface)	0.19
EQ Mag (Mw)	6.0

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Facility: KIF TDEC Stability
Project No.: 175668043
CPT ID: KIF-BF-CPT-5B

Water Elevation during CPT:	756.0	ft
Depth to Water during CPT:	13.0	ft *(relative to ground surface during CPT)*
Water Elevation during Earthquake:	754.0	ft
Depth to Water during Earthquake:	15.0	ft *(relative to ground surface during CPT)*
Final Grade Elevation during EQ:	766	ft *(if no fill, then set this equal to top of CPT hole elev.)*
Height of Final Grade above CPT TOH:	-3.0	ft *(relative to ground surface during CPT, + Fill, - Cut)*
Unit Weight of Cut/Fill to Achieve Final Grade	122	pcf
Cut/Fill Total Stress (+ Fill, - Cut):	-0.18	tsf

LIQUEFACTION POTENTIAL ASSESSMENT FOR COARSE GRAINED SOILS USING CONE PENETRATION TEST DATA

Project Site: **KIF TDEC Stability**
Stantec Project No.: **175668043**
CPT ID: **KIF-BF-CPT-5B**

Depth to Water during Earthquake:	15.0	ft
Final Grade Elevation during EQ:	766.0	ft
Height of Final Grade above CPT TOH:	-3.0	ft
Normalize K_σ to:	1.058	tsf
a_{max} at top of ground surface:	0.19	g
Earthquake Magnitude:	6.00	M_W
Earthquake File or Source Zone:	10	Hz

Shear Stress Fit Parameters

Adapted from "Discussion of 'Liquefaction Potential of Silts from CPTu'" (Robertson 2008). Zone A_1 and Zone A_2 samples are generally sand-like. Zone B samples are generally clay-like and not susceptible to cyclic softening. Zone C samples are generally clay-like and susceptible to cyclic softening. Note that the transition from clay-like to sand-like in this chart does not exactly match the liquefaction calculations herein; that is, some transitional samples in Zone B and Zone C will be treated as sand-like and analyzed for liquefaction if the calculations indicate as such.

3.6 SAMPLE CALCULATIONS

3.6.1 SPT Liquefaction Sample Calculation

SPT Liquefaction Analysis, Example Calculation

An example calculation for the factor of safety against liquefaction at a SPT sample point follows. Inputs and calculations are grouped by the sheets on which they appear in the calculation workbooks. A brief description is provided for each calculation/variable definition. Additionally, the cell reference associated with the calculation/definition is provided.

Example Calculations

Workbook Name: MCE-New Madrid_SiSALT_SPT_BEH-B1.xlsm
Workbook Sheet Name: Inputs & Constants
Calculations are not performed in this sheet; however, all inputs from field and laboratory data and ground response analyses are keyed-in here.

Calculation/Variable Definition:	Description:	Cell Location
Generic Inputs: **The following are keyed in for each boring**		
tsf := 2000psf	Variable definition for Mathcad calculations. No associated location in workbook.	
BoringID:= "BEH-B1"	The Stantec boring ID associated with the calculation.	B2
ID := 4.25in	The inside diameter of the boring.	B14
El_{TOH} := 476.6ft	The top of hole elevation of the boring during drilling.	B15
$D_{H20,drilling}$:= 20.5ft	The depth to water during drilling. Typically estimated from seepage analyses rather than field-measured values.	B16
$D_{samplingBegan}$:= 0.0ft	The depth SPT sampling began.	B17
$\gamma_{above1stSPT}$:= 0pcf	The total unit weight of material located above the first SPT sample.	B18
AssumedRodStickup:= 5ft	The assumed rod stickup during SPT testing.	B19
FvMethod := 1	Cell used to specify if the hammer efficiency measurement was based on the Fv method. A value of 1 indicates "Yes"; a value of 0 indicates "No". A value of 1 here results in a value of 1 for the "Rod Length Correction" value in sheet "part1".	B20
SampleLiners := 0	Cell used to specify if the SPT sampler contained liners. A value of 1 indicates "Yes"; a value of 0 indicates "No".	B21
$D_{H20,EQ}$:= 20.5ft	The depth to water (relative to the SPT top of hole) during the earthquake.	B24
$El_{FinalGrade}$:= 476.6ft	Final grade surface elevation during earthquake at the SPT boring location.	B25
$\gamma_{cut/fill}$:= 0pcf	Average unit weight of cut/fill to achieve final grade. Value is 0 if the final grade is unchanged from the grade during drilling.	B26

NonlinearPWP := 0	Cell used to specify if nonlinear pore water pressure distributions are used in the analysis. A value of 1 indicates Yes; a value of 0 indicates No. If 1 is keyed in, pore water pressure during drilling and during earthquake must be keyed in for each sample.	B29
AlphaAtEachSample := 1	Cell used to specify if alpha values at each sample depth are known. A value of 1 indicates "Yes"; a value of 0 indicates "No". If 1 is keyed in, alpha values must be keyed in for each sample. If 0 is keyed in, curve fit parameters must be keyed in for each sample.	B34
CSRFromShearStress := 0	Cell used to specify if CSR will be calculated from shear stress envelopes. A value of 1 indicates Yes"; a value of 0 indicates "No". If 1 is keyed in, shear stress values or curve fits must be keyed in. If 0 is keyed in, CSR will be calculated using rd method.	B45
$K_o := 0.5$	At rest lateral earth pressure coefficient.	X47 (Hidden)
$a_{max} := 0.4333g$	Peak ground acceleration at ground surface, from ground response analysis.	B58
$M_w := 7.8$	Magnitude (Mw) of analyzed earthquake.	B59
$\gamma_w := 62.4pcf$	Unit weight of water.	X3 (Hidden)
$p_a := 1.058tsf$	Atmospheric pressure.	X8 (Hidden)

Sample Inputs:
The following information is keyed in for each SPT sample.

$D_{aboveSample} := 27.3ft$	The depth of the sample immediately above the sample of interest.	E28
$D_{sample} := 28.8ft$	Midpoint depth of the sample of interest.	E29
$D_{belowSample} := 30.3ft$	The depth of the sample immediately below the sample of interest.	E30
$NValue := 12$	SPT N blow count associated with sample.	F29
$E_m := 93.8\%$	The measured or assumed hammer efficiency, for use in blow count correction.	G29
$USCS_Class := "SM"$	The measured or assumed USCS soil classification associated with the sample.	H29
$FinesContent := 32.4\%$	The measured or assumed fines content associated with the sample.	I29
$\gamma_{sampleAbove} := 122pcf$	The unit weight associated with the sample immediately above the sample of interest.	J28
$\gamma_{sample} := 122pcf$	The unit weight associated with the sample.	J29
$MaterialName := "Abutment sand"$	The material name associated with the sample.	M29
$ClaySandOverride := "Sand-like"$	Must be either "clay-like", "sand-like", or blank. If blank, clay-like or sand-like determination will be made based on soil classification. Overrides are typically keyed-in to account for the results of the clay-like/sand-like determination performed using laboratory and/or CPT data.	N29
$ClayLikeSusc := ""$	Must be "susceptible", "not susceptible", or blank. Value should be blank for sand-like samples. This value is only used in plotting features and not in the calculations presented herein.	O29
$\alpha := 0.018$	Static shear stress ratio associated with the sample. Value is calculated from SIGMA/W data for each sample.	P29

Workbook Sheet Name: part1

Calculations related to stress during sampling, blow count correction, and relative density are located in this sheet. Note that some stress calculations rely on values from adjacent samples. To simplify the presentation of these calculations, stresses and soil thicknesses of adjacent samples are defined here; though, they are calculated in a similar manner to the sample of interest. Some calculations from 'part2' are presented here as they are part of an iterative calculation. The relative state parameter is calculated in this sheet in the workbook; however, it is shown in 'part2' in this example calculation.

Calculation/Variable Definition:	Description:	Cell Location
Generic Calculations:		
The following is calculated for each boring.		
$El_{H20,drilling} := El_{TOH} - D_{H20,drilling}$ $El_{H20,drilling} = 456.1\,ft$	The calculated elevation of the water table during sampling.	H12
$El_{H20,EQ} := El_{TOH} - D_{H20,EQ}$ $El_{H20,EQ} = 456.1\,ft$	The calculated elevation of the water table during the associated earthquake.	H14
$\sigma_{v,above1st,soil,drilling} := \gamma_{above1stSPT} \cdot D_{samplingBegan}$ $\sigma_{v,above1st,soil,drilling} = 0 \cdot tsf$	The calculated total stress due to soil above the 1st SPT.	F16 (Hidden)
$\sigma_{v,H20} := \max\left(0, -1 \cdot D_{H20,drilling} \cdot \gamma_w\right)$ $\sigma_{v,H20} = 0 \cdot tsf$	The calculated total stress due to standing water above the ground surface. Value is 0 if depth to water is positive.	G17 (Hidden)
$\sigma_{v,above1st,drilling} := \sigma_{v,above1st,soil,drilling} + \sigma_{v,H20}$ $\sigma_{v,above1st,drilling} = 0 \cdot tsf$	The calculated total stress due to soil and water above the 1st SPT sample.	H16
$u_{above1st,drilling} := \max\left[0, \left(D_{samplingBegan} - D_{H20,drilling}\right) \cdot \gamma_w\right]$ $u_{above1st,drilling} = 0 \cdot tsf$	The calculated pore water pressure at the depth sampling began.	I16
$\sigma'_{v,above1st,drilling} := \sigma_{v,above1st,drilling} - u_{above1st,drilling}$ $\sigma'_{v,above1st,drilling} = 0 \cdot tsf$	The calculated vertical effective stress at the depth sampling began.	J16

Sample Calculations:
The following information is calculated for each SPT sample.

Calculation/Variable Definition:	Description:	Cell Location
$El_{sample} := El_{TOH} - D_{sample}$	The calculated elevation of the sample.	A33
$El_{sample} := 447.9ft$		
$D_{topInterval} := \frac{(D_{sample} + D_{aboveSample})}{2}$		
$D_{topInterval} := 28ft$	The calculated depth of the top of the "sampling interval", which corresponds to the depth halfway between adjacent samples.	D33 (Hidden)
$D_{bottomInterval} := \frac{(D_{sample} + D_{belowSample})}{2}$		
$D_{bottomInterval} := 29.5ft$	The calculated depth of the bottom of the "sampling interval", which corresponds to the depth halfway between adjacent samples.	D34 (Hidden)
$T_{interval} := D_{bottomInterval} - D_{topInterval}$		
$T_{interval} = 1.5 \cdot ft$	The calculated thickness of the "sampling interval".	E33 (Hidden)
$\sigma_{v,aboveSample,drilling} := 1.79475tsf$	The total stress during drilling at the midpoint of the sample above the sample of interest.	F32
$D_{topInterval,aboveSample} := 26.5ft$	The top of the "sampling interval" of the sample above the sample of interest.	D32 (Hidden)
$T_{interval.aboveSample} := 1.5ft$	The thickness of the "sampling interval" of the sample above the sample of interest.	E32 (Hidden)
$\sigma_{v,soil,sample,drilling} := \sigma_{v,aboveSample,drilling} \cdots + \left[\begin{pmatrix} D_{topInterval,aboveSample} + T_{interval.aboveSample} \cdots \\ + -D_{aboveSample} \end{pmatrix} \cdot \gamma_{sampleAbove} \cdots + \left(D_{sample} - D_{topInterval}\right) \cdot \gamma_{sample} \right]$		
$\sigma_{v,soil,sample,drilling} := 1.88625tsf$	The total stress during drilling due to soil at the midpoint of the sample of interest.	F33 (Hidden)

$\sigma_{v,sample,drilling} := \sigma_{v,soil,sample,drilling} + \sigma_{v,H20}$

$\sigma_{v,sample,drilling} := 1.89tsf$ The total stress during drilling due to soil and standing water at the midpoint of the sample of interest. H33

$u_{sample,drilling} := \max\left(0, D_{sample} - D_{H20,drilling}\right) \cdot \gamma_w$

$u_{sample,drilling} := 0.26tsf$ The pore water pressure during drilling at the midpoint of the sample of interest. I33

$\sigma'_{v,sample,drilling} := \sigma_{v,sample,drilling} - u_{sample,drilling}$

$\sigma'_{v,sample,drilling} = 1.63 \cdot tsf$ The vertical effective stress during drilling at the midpoint of the sample of interest. J33

$$C_B := \text{if}\left(ID > 8in, 1.150, \text{if}\left(ID > 6in, \frac{ID}{in \cdot 20} + 0.75, \text{if}\left(ID > 4.5in, \frac{ID}{in \cdot 30} + .85, 1\right)\right)\right)$$

$C_B = 1$ Borehole diameter correction. M33

$C_R := 1$ Rod length correction. Value is 1 if Fv energy measurement is specified. O33

$$C_E := \frac{E_m}{60\%} = 1.563$$ Hammer energy correction factor Q33

$$\Delta N_{1,60cs} := \exp\left[1.63 - \left(\frac{15.7}{FinesContent \cdot 100 + .01}\right)^2 + \frac{9.7}{FinesContent \cdot 100 + .01}\right]$$

$\Delta N_{1,60cs} := 5.44$ Clean sand correction value. Note that this value is calculated in 'part2' but presented here as it is part of the iterative calculation shown below. part2,I33 (hidden)

The following parameters require iterative calculations. In the Excel workbook, iterative calculations are enabled, and a macro is used to provide initial guesses.

$$C_S = \min\left(1.3, \max\left(1.1, 1 + \frac{N_{1,60}}{100}\right)\right)$$

$C_S := 1.19$ Sampler correction factor. N33

$$C_N = \min\left[\left(\frac{p_a}{\sigma'_{v,sample,drilling}}\right)^{0.784 - 0.521 \cdot D_r}, 1.7\right]$$

$C_N := 0.84$ Overburden stress correction factor P33

$N_{60} := NValue \cdot C_E \cdot C_B \cdot C_R \cdot C_S$

$N_{60} := 22.265$

Corrected blow count for the sample of interest. R33

$N_{1,60} := C_N \cdot N_{60}$

$N_{1,60} := 18.681$

Normalized blow count for the sample of interest. S33

$N_{1,60cs} := N_{1,60} + \Delta N_{1,60cs}$

$N_{1,60cs} := 24.126$

Equivalent clean sand N-value for the sample of interest. Note that this calculation appears on 'part2' but is included here since it is a part of the iterative calculation. part2, J33

$D_r := \min\left(1, \sqrt{\frac{N_{1,60cs}}{46}}\right) = 72.421\,\%$

Relative density of the sample of interest. T33

End of iterative calculation

Workbook Sheet Name: part2

Calculations related to stresses during the earthquake event, cyclic stress ratio (CSR), cyclic resistance ratio (CRR), and factor of safety against liquefaction are located in this sheet. Note that the relative state parameter is also calculated here, as it relies on the effective stress during the earthquake event.

Generic Calculations:

The following is calculated for each boring.

Calculation/Variable Definition:	Description:	Cell Location
$\sigma_{v,fill} := \left(El_{FinalGrade} - El_{TOH}\right)\cdot\gamma_{cut/fill}$		
$\sigma_{v,fill} = 0$	The added total stress due to cut/fill after drilling but before the earthquake event.	F14
$\sigma_{v,above1st,soil,EQ} := \sigma_{v,above1st,soil,drilling} + \sigma_{v,fill}$		
$\sigma_{v,above1st,soil,EQ} = 0\cdot tsf$	The calculated total stress due to soil above the 1st SPT during the earthquake.	B16 (Hidden)
$\sigma_{v,H20,EQ} := \max\left(0, -1\cdot D_{H20,EQ}\cdot\gamma_w\right)$ $\sigma_{v,H20,EQ} = 0\cdot tsf$	The calculated total stress due to standing water above the ground surface during the earthquake. Value is 0 if depth to water is positive.	C16 (Hidden)
$\sigma_{v,above1st,EQ} := \sigma_{v,above1st,soil,EQ} + \sigma_{v,H20,EQ}$		
$\sigma_{v,above1st,EQ} = 0\cdot tsf$	The calculated total stress due to soil and water above the 1st SPT sample.	D16
$u_{above1st,EQ} := \max\left[0, \left(D_{samplingBegan} - D_{H20,EQ}\right)\cdot\gamma_w\right]$		
$u_{above1st,EQ} = 0\cdot tsf$	The calculated pore water pressure at the depth sampling began during the earthquake.	E16
$\sigma'_{v,above1st,EQ} := \sigma_{v,above1st,EQ} - u_{above1st,EQ}$		
$\sigma'_{v,above1st,EQ} = 0\cdot tsf$	The calculated vertical effective stress at the depth sampling began during the earthquake.	F16

Sample Calculations:
The following information is calculated for each SPT sample.

Calculation/Variable Definition:	Description:	Cell Location

$\sigma_{v,soil,sample,EQ} := \sigma_{v,soil,sample,drilling} + \sigma_{v,fill}$

$\sigma_{v,soil,sample,EQ} := 1.89tsf$ — The total stress during the earthquake due to soil at the midpoint of the sample of interest. — B33

$\sigma_{v,sample,EQ} := \sigma_{v,soil,sample,EQ} + \sigma_{v,H20,EQ}$

$\sigma_{v,sample,EQ} = 1.89 \cdot tsf$ — The total stress during the earthquake due to soil and standing water at the midpoint of the sample of interest. — D33

$u_{sample,EQ} := \max\left(0, D_{sample} - D_{H20,EQ}\right) \cdot \gamma_w$

$u_{sample,EQ} := 0.26tsf$ — The pore water pressure during the earthquake at the sample of interest. — E33

$\sigma'_{v,sample,EQ} := \sigma_{v,sample,EQ} - u_{sample,EQ}$

$\sigma'_{v,sample,EQ} = 1.63 \cdot tsf$ — The vertical effective stress during the earthquake at the midpoint of the sample of interest. — F33

$$\Delta N_{1,60cs} = \exp\left[1.63 - \left(\frac{15.7}{FinesContent \cdot 100 + .01}\right)^2 + \frac{9.7}{FinesContent \cdot 100 + .01}\right]$$

$\Delta N_{1,60cs} := 5.44$ — Clean sand correction value. (Also presented in 'part1' as part of iterative calculations.) — I33

$N_{1,60cs} = N_{1,60} + \Delta N_{1,60cs}$

$N_{1,60cs} := 24.126$ — Equivalent clean sand N-value for the sample of interest. (Also presented in 'part1' as part of iterative calculations.) — J33

$$\xi_R := \max\left[-0.6, \min\left[\frac{1}{\left[10 - \ln\left[100 \cdot \left(1 + 2 \cdot K_o\right) \cdot \frac{\sigma'_{v,sample,EQ}}{3 \cdot p_a}\right]\right]} - D_r, 0.1\right]\right]$$

$\xi_R := -0.54$ — Relative state parameter index calculation at the sample of interest. Note that this is from part1, but shown here since it relies on effective stress calculations during the EQ — part1, X33

$$CRR_{7.5} := \exp\left[\frac{N_{1,60cs}}{14.1} + \left(\frac{N_{1,60cs}}{126}\right)^2 - \left(\frac{N_{1,60cs}}{23.6}\right)^3 + \left(\frac{N_{1,60cs}}{25.4}\right)^4 - 2.8\right]$$

$CRR_{7.5} = 0.271$ — Cyclic Resistance Ratio of the sample of interest. — K33

$$C_\sigma := \min\left(0.3, \frac{1}{18.9 - 17.3 \cdot D_r}\right)$$ Supporting parameter for overburden correction factor. L33 (Hidden)

$C_\sigma := 0.157$

$$K_\sigma := \min\left(1.1, 1 - C_\sigma \cdot \ln\left(\frac{\sigma'_{v,sample,EQ}}{p_a}\right)\right)$$

$K_\sigma := 0.932$ Overburden correction factor at the sample of interest. M33

$$a := 1267 + 636 \cdot \alpha^2 - 634 \cdot \exp(\alpha) - 632 \exp(-\alpha)$$

$a := 0.965$ Supporting parameter for static shear stress correction. N33 (Hidden)

$$b := \exp\left(-1.11 + 12.3\alpha^2 + 1.31 \ln(\alpha + .0001)\right)$$

$b := 0.002$ Supporting parameter for static shear stress correction. O33 (Hidden)

$c_\alpha := 0.138 + .126\alpha + 2.52\alpha^3$ Supporting parameter for static shear stress correction. P33 (Hidden)

$c_\alpha := 0.140$

$$K_\alpha := a + b \cdot \exp\left(\frac{-\xi_R}{c_\alpha}\right)$$ Static shear stress correction factor at the sample of interest. Q33

$K_\alpha := 1.044$

$$MSF_{max} := \min\left[2.2, 1.09 + \left(\frac{N_{1,60cs}}{31.5}\right)^2\right]$$

$MSF_{max} := 1.6766$ Supporting parameter for magnitude scaling factor. R33 (Hidden)

$$MSF := 1 + \left(MSF_{max} - 1\right) \cdot \left(8.64 \cdot \exp\left(\frac{-M_w}{4}\right) - 1.325\right)$$

$MSF := 0.94$ Magnitude scaling factor at the sample of interest. S33

$CRR := CRR_{7.5} \cdot MSF \cdot K_\sigma \cdot K_\alpha$

$CRR := 0.246$ Corrected cyclic resistance ratio at the sample of interest. T33

$$\alpha_z := -1.012 - 1.126 \cdot \sin\left[\left(\frac{D_{sample} + El_{FinalGrade} - El_{TOH}}{11.73m}\right) + 5.133\right]$$

$\alpha_{zz} := -0.570$ Supporting parameter for the stress reduction coefficient. U33 (Hidden)

$$\beta_z := .106 + .118 \cdot \sin\left[\left(\frac{D_{sample} + El_{FinalGrade} - El_{TOH}}{11.28m}\right) + 5.142\right]$$

$\beta_{zz} := 0.064$ Supporting parameter for the stress reduction coefficient. V33 (Hidden)

$r_d := \exp(\alpha_z + \beta_z \cdot M_w)$

$r_{dv} := 0.931$ Stress reduction coefficient at the sample of interest. W33

$$CSR := 0.65 \cdot \left(\frac{\sigma_{v,sample,EQ}}{\sigma'_{v,sample,EQ}}\right) \cdot \left(\frac{a_{max}}{g}\right) \cdot r_d$$

$CSR := 0.304$ Cyclic stress ratio at the sample of interest. X33 (Hidden), also shown in AD33

$Screen_{clay\text{-}like} := if(ClaySandOverride = "Clay\text{-}like", "TRUE", "FALSE")$

$Screen_{clay\text{-}like} = "FALSE"$ Boolean to determine if sample has been classified as clay-like or sand-like. If sample is clay-like, it is screened out from liquefaction. AE33

$Screen_{HighN} := if(N_{1,60cs} \geq 32, "TRUE", "FALSE")$

$Screen_{HighN} = "FALSE"$ Boolean to determine if sample has a sufficiently high clear sand equivalent blow count. If N1,60cs exceeds 32, the sample is screened out from liquefaction. AF33

$Screen_{unsat} := if(D_{H20,EQ} > D_{sample}, "TRUE", "FALSE")$

$Screen_{unsat} = "FALSE"$ Boolean to determine if sample is unsaturated. Unsaturated samples are screened out from liquefaction. AG33

$$FS_{liq} := \begin{cases} \text{"N/A"} & \text{if } Screen_{unsat} = \text{"TRUE"} \\ \text{"N/A"} & \text{if } Screen_{HighN} = \text{"TRUE"} \\ \text{"N/A"} & \text{if } Screen_{clay\text{-}like} = \text{"TRUE"} \\ \text{round}\left[\left(\frac{CRR}{CSR}\right), 1\right] & \text{otherwise} \end{cases}$$

Factor of safety against liquefaction calculation. Factor of safety is not calculated if the material was screened out. Additionally, the value is rounded to the nearest tenth.

AH33

$FS_{liq} := 0.8$

3.6.2 CPT Liquefaction Sample Calculation

CPT Liquefaction Analysis, Example Calculation

An example calculation for the factor of safety against liquefaction at a CPT sample point follows. Inputs and calculations are grouped by the sheets on which they appear in the calculation workbooks. A brief description is provided for each calculation/variable definition. Additionally, the cell reference associated with the calculation/definition is provided.

Example Calculations

Workbook Name: MCE-New Madrid_SiSALT_CPT_BEH-C1.xlsm
Workbook Sheet Name: Inputs & Constants
Calculations are not performed in this sheet; however, all inputs from field and laboratory data and ground response analyses are keyed-in here.

Calculation/Variable Definition:	Description:	Cell Location
Generic Inputs: **The following are keyed in for each sounding**		
tsf := 2000psf	Variable definition for Mathcad calculations. No associated location in workbook	
CPT_ID := "BEH-C1"	The Stantec CPT ID associated with the calculation.	B4
El_{TOH} := 476.9ft	The top of hole elevation during CPT.	B21
$D_{H20,CPT}$:= 21.6ft	The depth to water during CPT. Typically estimated from seepage analyses rather than field-measured values.	B22
$D_{samplingBegan}$:= 0.0ft	The depth CPT sampling began.	B23
$\gamma_{above1stSample}$:= 0pcf	The total unit weight of material located above the first CPT sample. Value is 0 if sampling began at the surface.	B24
$D_{H20,EQ}$:= 21.6ft	The depth to water (relative to the CPT top of hole) during the earthquake.	B27
$El_{FinalGrade}$:= 476.9ft	Final grade suface elevation during earthquake at the CPT boring location.	B28
$\gamma_{cut/fill}$:= 0pcf	Average unit weight of cut/fill to achieve final grade. Value is 0 if the final grade is unchanged from the grade during drilling.	B29
NonlinearPWP := 0	Cell used to specify if nonlinear pore water pressure distributions are used in the analysis. A value of 1 indicates Yes; a value of 0 indicates No. If 1 is keyed in, pore water pressure during drilling and during earthquake must be keyed in for each sample.	B32
AlphaAtEachSample := 1	Cell used to specify if alpha values at each sample depth are known. A value of 1 indicates "Yes"; a value of 0 indicates "No". If 1 is keyed in, alpha values must be keyed in for each sample. If 0 is keyed in, curve fit parameters must be keyed in for each sample.	B37

CSRFromShearStress := 0	Cell used to specify if CSR will be calculated from shear stress envelopes. A value of 1 indicates Yes"; a value of 0 indicates "No". If 1 is keyed in, shear stress values or curve fits must be keyed in. If 0 is keyed in, CSR will be calculated using rd method.	B48
$K_o := 0.5$	At rest lateral earth pressure coefficient.	V25 (Hidden)
$a_{max} := 0.4577g$	Peak ground acceleration value at ground surface, from ground response analysis.	B61
$M_w := 7.8$	Magnitude (Mw) of analyzed earthquake.	B62
$\gamma_w := 62.4pcf$	Unit weight of water.	V21 (Hidden)
$p_a := 1.058tsf$	Atmospheric pressure.	V22 (Hidden)

Sample Inputs:
The following information is keyed in for each CPT sample.

$D_{aboveSample} := 70.487ft$	The depth of the sample immediately above the sample of interest.	E564
$D_{sample} := 70.565ft$	Midpoint depth of the sample of interest.	E565
$D_{belowSample} := 70.645ft$	The depth of the sample immediately below the sample of interest.	E566
$q_t := 105.197tsf$	Corrected cone tip resistance associated with sample.	F565
$f_s := 3.011tsf$	Sleeve friction associated with sample.	G565
$\gamma_{sampleAbove} := 122pcf$	The unit weight associated with the sample immediately above the sample of interest.	I564
$\gamma_{sample} := 122pcf$	The unit weight associated with the sample.	I565
MaterialName := "Foundation Sands"	The material name associated with the sample.	J565
ClaySandOverride := ""	Must be either "clay-like", "sand-like" or blank. If blank, clay-like or sand-like determination will be made based on soil behavior type. Overrides are typically keyed-in to account for the results of the clay-like/sand-like determination performed using laboratory and/or CPT data.	K565
$\alpha := 0.07719$	Static shear stress ratio associated with the sample. Value is calculated from SIGMA/W data for each sample.	M565

Workbook Sheet Name: Field Data & Stresses

Calculations related to stress during sampling and during earthquake are located in this sheet. Note that some stress calculations rely on values from adjacent samples. To simplify the presentation of these calculations, stresses and soil thicknesses of adjacent samples are defined here; though, they are actually calculated in a similar manner to the sample of interest in the workbook.

Calculation/Variable Definition:	Description:	Cell Location
Generic Calculations:		
The following is calculated for each boring.		
$El_{H20,CPT} := El_{TOH} - D_{H20,CPT}$ $El_{H20,CPT} = 455.3 \cdot ft$	The calculated elevation of the water table during CPT sampling.	J3
$El_{H20,EQ} := El_{TOH} - D_{H20,EQ}$ $El_{H20,EQ} = 455.3 \cdot ft$	The calculated elevation of the water table during the associated earthquake.	J5
$\sigma_{v,above1st,soil,CPT} := \gamma_{above1stSample} \cdot D_{samplingBegan}$ $\sigma_{v,above1st,soil,CPT} = 0 \cdot tsf$	The calculated total stress due to soil above the 1st sample during CPT sampling.	H17 (Hidden)
$\sigma_{v,H20} := \max(0, -1 \cdot D_{H20,CPT} \cdot \gamma_w)$ $\sigma_{v,H20} = 0 \cdot tsf$	The calculated total stress due to standing water above the ground surface during CPT sampling. Value is 0 if depth to water is positive.	I17 (Hidden)
$\sigma_{v,above1st,CPT} := \sigma_{v,above1st,soil,CPT} + \sigma_{v,H20}$ $\sigma_{v,above1st,CPT} = 0 \cdot tsf$	The calculated total stress due to soil and water above the 1st CPT sample during CPT sampling.	J17
$u_{above1st,CPT} := \max[0, (D_{samplingBegan} - D_{H20,CPT}) \cdot \gamma_w]$ $u_{above1st,CPT} = 0 \cdot tsf$	The calculated pore water pressure at the depth sampling began during CPT sampling.	N17
$\sigma'_{v,above1st,CPT} := \sigma_{v,above1st,CPT} - u_{above1st,CPT}$ $\sigma'_{v,above1st,CPT} = 0 \cdot tsf$	The calculated vertical effective stress at the depth sampling began during CPT sampling.	P17

$\sigma_{v,fill} := \left(El_{FinalGrade} - El_{TOH}\right) \cdot \gamma_{cut/fill}$

$\sigma_{v,fill} = 0$ The added total stress due to cut/fill after drilling but before the earthquake event. J10

$\sigma_{v,above1st,soil,EQ} := \sigma_{v,above1st,soil,CPT} + \sigma_{v,fill}$

$\sigma_{v,above1st,soil,EQ} = 0 \cdot tsf$ The calculated total stress due to soil above the 1st CPT during the earthquake. K17 (Hidden)

$\sigma_{v,H20,EQ} := \max\left(0, -1 \cdot D_{H20,EQ} \cdot \gamma_w\right)$

$\sigma_{v,H20,EQ} = 0 \cdot tsf$ The calculated total stress due to standing water above the ground surface during the earthquake. Value is 0 if depth to water is positive. L17 (Hidden)

$\sigma_{v,above1st,EQ} := \sigma_{v,above1st,soil,EQ} + \sigma_{v,H20,EQ}$

$\sigma_{v,above1st,EQ} = 0 \cdot tsf$ The calculated total stress due to soil and water above the 1st CPT sample during the earthquake. M17

$u_{above1st,EQ} := \max\left[0, \left(D_{samplingBegan} - D_{H20,EQ}\right) \cdot \gamma_w\right]$

$u_{above1st,EQ} = 0 \cdot tsf$ The calculated pore water pressure at the depth sampling began during the earthquake. O17

$\sigma'_{v,above1st,EQ} := \sigma_{v,above1st,EQ} - u_{above1st,EQ}$

$\sigma'_{v,above1st,EQ} = 0 \cdot tsf$ The calculated vertical effective stress at the depth sampling began during the earthquake. Q17

Sample Calculations:
The following information is calculated for each CPT sample.

Calculation/Variable Definition:	Description:	Cell Location
$El_{sample} := El_{TOH} - D_{sample}$	The calculated elevation of the sample.	A568

El.sample := 406.3 ft

$$D_{topInterval} := \frac{\left(D_{sample} + D_{aboveSample}\right)}{2}$$

$D_{topInterval} = 70.526 \cdot ft$	The calculated depth of the top of the "sampling interval", which corresponds to the depth halfway between adjacent samples.	F568

$$D_{bottomInterval} := \frac{\left(D_{sample} + D_{belowSample}\right)}{2}$$

$D_{bottomInterval} = 70.605 \cdot ft$	The calculated depth of the bottom of the "sampling interval", which corresponds to the depth halfway between adjacent samples.	F569

$T_{interval} := D_{bottomInterval} - D_{topInterval}$

$T_{interval} = 0.079 \cdot ft$	The calculated thickness of the "sampling interval".	G568

$\sigma_{v,aboveSample,CPT} := 4.5593tsf$	The total stress during CPT at the midpoint of the sample above the sample of interest.	H567 (Hidden)
$D_{topInterval,aboveSample} := 70.4504ft$	The top of the "sampling interval" of the sample above the sample of interest.	F567
$T_{interval.aboveSample} := 0.0755ft$	The thickness of the "sampling interval" of the sample above the sample of interest.	G567

$$\sigma_{v,soil,sample,CPT} := \sigma_{v,aboveSample,CPT} \cdots + \left[\begin{pmatrix} D_{topInterval,aboveSample} + T_{interval.aboveSample} \cdots \\ + -D_{aboveSample} \end{pmatrix} \cdot \gamma_{sampleAbove} \cdots + \left(D_{sample} - D_{topInterval}\right) \cdot \gamma_{sample}\right]$$

$\sigma_{v,soil,sample,CPT} = 4.564 \cdot tsf$	The total stress during drilling due to soil at the midpoint of the sample of interest.	H568

$\sigma_{v,sample,CPT} := \sigma_{v,soil,sample,CPT} + \sigma_{v,H20}$

$\sigma_{v,sample,CPT} = 4.564 \cdot tsf$ The total stress during drilling due to soil and standing water at the midpoint of the sample of interest. J568

$u_{sample,CPT} := \max\left(0, D_{sample} - D_{H20,CPT}\right) \cdot \gamma_w$

$u_{sample,CPT} = 1.528 \cdot tsf$ The pore water pressure during drilling at the midpoint of the sample of interest. N568

$\sigma'_{v,sample,CPT} := \sigma_{v,sample,CPT} - u_{sample,CPT}$

$\sigma'_{v,sample,CPT} = 3.036 \cdot tsf$ The vertical effective stress during drilling at the midpoint of the sample of interest. P568

$\sigma_{v,soil,sample,EQ} := \sigma_{v,soil,sample,CPT} + \sigma_{v,fill}$

$\sigma_{v,soil,sample,EQ} = 4.564 \cdot tsf$ The total stress during the earthquake due to soil at the midpoint of the sample of interest. K568

$\sigma_{v,sample,EQ} := \sigma_{v,soil,sample,EQ} + \sigma_{v,H20,EQ}$

$\sigma_{v,sample,EQ} = 4.564 \cdot tsf$ The total stress during the earthquake due to soil and standing water at the midpoint of the sample of interest. M568

$u_{sample,EQ} := \max\left(0, D_{sample} - D_{H20,EQ}\right) \cdot \gamma_w$

$u_{sample,EQ} = 1.528 \cdot tsf$ The pore water pressure during the earthquake at the sample of interest. O568

$\sigma'_{v,sample,EQ} := \sigma_{v,sample,EQ} - u_{sample,EQ}$

$\sigma'_{v,sample,EQ} = 3.036 \cdot tsf$ The vertical effective stress during the earthquake at the midpoint of the sample of interest. Q568

Workbook Sheet Name: qc1n, F, Ic

Calculations related to tip resistance correction and normalization are in this sheet. The relative state parameter is also calculated here.

Sample Calculations:
The following information is calculated for each CPT sample.

Calculation/Variable Definition:	Description:	Cell Location
$F := \frac{f_s}{q_t - \sigma_{v,sample,CPT}}$	The normalized friction ratio.	G568

$F = 2.992 \cdot \%$

Calculation of the the normalized cone resistance (Q) is calculated below. As part of the calculation, three values of 'n' are selected. For each assumed value of n, Q and the soil behavior type index (Ic) are calculated. First, n is assumed to be 1.0 and then Q and Ic are calculated. If the calculated Ic value is greater than 2.6, then n = 1.0 is selected. If this Ic value is less than 2.6, then Q and Ic are calculated assuming n is 0.5. If this Ic value is less than 2.6, then n = 0.5 is selected. If this Ic is greater than 2.6, then n = 0.7 is selected. Q and Ic are reported for the selected n value at each sample.

$n := 1.0$ Assumed value of n for use in calculation of Q and Ic. H16 (Hidden)

$$Q_1 := \left[\frac{\left(q_t - \sigma_{v,sample,CPT}\right)}{p_a}\right] \cdot \left(\frac{p_a}{\sigma'_{v,sample,CPT}}\right)^n$$

$Q_1 = 33.143$ Test Q value assuming n = 1.0. C568 (Hidden)

$$I_{c1} := \left[\left(3.47 - \log\left(Q_1\right)\right)^2 + (1.22 + \log(F \cdot 100))^2\right]^{0.5}$$

$I_{c1} = 2.584$ Test Ic value assuming n = 1.0. H568 (Hidden)

$n := 0.5$ Assumed value of n for use in calculation of Q and Ic. I16 (Hidden)

$$Q_5 := \left[\frac{\left(q_t - \sigma_{v,sample,CPT}\right)}{p_a}\right] \cdot \left(\frac{p_a}{\sigma'_{v,sample,CPT}}\right)^n$$

$Q_5 = 56.146$ Test Q value assuming n = 0.5. D568 (Hidden)

$$I_{c5} := \left[\left(3.47 - \log\left(Q_5\right)\right)^2 + (1.22 + \log(F \cdot 100))^2\right]^{0.5}$$

$I_{c5} = 2.416$ Test Ic value assuming n = 0.5. I568 (Hidden)

$n := 0.7$ Assumed value of n for use in calculation of Q and Ic. J16 (Hidden)

$$Q_7 := \left[\frac{\left(q_t - \sigma_{v,sample,CPT}\right)}{p_a}\right] \cdot \left(\frac{p_a}{\sigma'_{v,sample,CPT}}\right)^n$$

$Q_7 = 45.472$ Test Q value assuming n = 0.7. E568 (Hidden)

$$I_{c7} := \left[\left(3.47 - \log\left(Q_7\right)\right)^2 + (1.22 + \log(F \cdot 100))^2\right]^{0.5}$$

$I_{c7} = 2.482$ Test Ic value assuming n = 0.7. J568 (Hidden)

$$n := \begin{cases} 1.0 & \text{if } I_{c1} > 2.6 \\ 0.5 & \text{if } I_{c5} < 2.6 \\ 0.7 & \text{otherwise} \end{cases}$$

Selected n value. L568

$n = 0.5$

$$Q := \left[\frac{\left(q_t - \sigma_{v,sample,CPT}\right)}{p_a}\right] \cdot \left(\frac{p_a}{\sigma'_{v,sample,CPT}}\right)^n$$

$Q = 56.146$ Q value using assigned n value. F568

$$I_c := \left[(3.47 - \log(Q))^2 + (1.22 + \log(F \cdot 100))^2\right]^{0.5}$$

$I_c = 2.416$ Ic value using assigned n value K568

End of Ic, Q calculation

$FC := 80 \cdot I_c - 137$ Fines content calculation O568

$FC = 56.28$

The following parameters require iterative calculations. In the Excel workbook, iterative calculations are enabled, and a macro is used to provide initial guesses.

$$C_N = \min\left[1.7, \left[\frac{p_a}{\left(\sigma_{v,sample,CPT}\right)}\right]^{0.784 - 0.521 D_r}\right]$$

$C_N := 0.6$ Normalizing factor for CPT resistance. M568

$$q_{c1N} := C_N \cdot \frac{q_t}{p_a}$$

Normalized average cone tip resistance. N568

$q_{c1N} := 62.379$

$$\Delta q_{c1N} := \left(11.9 + \frac{q_{c1N}}{14.6}\right) \exp\left[1.63 - \left(\frac{9.7}{FC + 2}\right) - \left(\frac{15.7}{FC + 2}\right)^2\right]$$

$\Delta q_{c1N} = 64.995$ Clean sand correction. P568 (Hidden)

$$q_{c1Ncs} := q_{c1N} + \Delta q_{c1N}$$

$q_{c1Ncs} = 127.374$ Clean sand normalized average cone tip resistance Q568

$$D_r := \min\left[1, 0.465\left(\frac{q_{c1Ncs}}{0.9}\right)^{0.264} - 1.063\right] = 65.599 \cdot \%$$

$D_r = 65.599 \cdot \%$ Relative density of the sample of interest. From sheet "FS LIQ" but shown here to support calculations in this sheet. Sheet: FS LIQ Cell: D568

End of iterative calculation

$$\xi_R := \max\left[-0.6, \min\left[\frac{1}{\left[10 - \ln\left[100 \cdot \left(1 + 2 \cdot K_o\right) \cdot \frac{\sigma'_{v,sample,EQ}}{3 \cdot p_a}\right]\right]} - D_r, 0.1\right]\right]$$

$\xi_R = -0.445$ Relative state parameter index calculation at the sample of interest. S568

Workbook Sheet Name: FS LIQ

Calculations related to stresses during the earthquake event, cyclic stress ratio (CSR), cyclic resistance ratio (CRR), and factor of safety against liquefaction are located in this sheet.

Sample Calculations:

The following information is calculated for each CPT sample.

Calculation/Variable Definition:	Description:	Cell Location

$$CRR_{7.5} := \exp\left[-2.8 + \left(\frac{q_{c1Ncs}}{137}\right)^4 + \left[-\left(\frac{q_{c1Ncs}}{140}\right)\right]^3 + \left(\frac{q_{c1Ncs}}{1000}\right)^2 + \frac{q_{c1Ncs}}{113}\right]$$

$CRR_{7.5} = 0.19$ Cyclic resistance ratio for the sample of interest. C568

$$D_r := \min\left[1, 0.465\left(\frac{q_{c1Ncs}}{0.9}\right)^{0.264} - 1.063\right] = 65.599\cdot\%$$

$D_r = 65.599\cdot\%$ Relative density of the sample of interest. D568

$$C_\sigma := \min\left(0.3, \frac{1}{18.9 - 17.3\cdot D_r}\right)$$

Supporting parameter for overburden correction factor. E568 (Hidden)

$C_\sigma = 0.132$

$$K_\sigma := \min\left(1.1, 1 - C_\sigma\cdot\ln\left(\frac{\sigma'_{v,sample,EQ}}{p_a}\right)\right)$$

$K_\sigma = 0.86$ Overburden correction factor at the sample of interest. F568

$$a := 1267 + 636\cdot\alpha^2 - 634\cdot\exp(\alpha) - 632\exp(-\alpha)$$

$a = 0.861$ Supporting parameter for static shear stress correction. G568 (Hidden)

$$b := \exp\left(-1.11 + 12.3\alpha^2 + 1.31\ln(\alpha + .0001)\right)$$

$b = 0.012$ Supporting parameter for static shear stress correction. H568 (Hidden)

$c_\alpha := 0.138 + .126\alpha + 2.52\alpha^3$ Supporting parameter for static shear stress correction. I568 (Hidden)

$c_\alpha = 0.149$

$$K_\alpha := a + b \cdot \exp\left(\frac{-\xi_R}{c_\alpha}\right)$$

$K_\alpha = 1.108$

Static shear stress correction factor at the sample of interest. J568

$$MSF_{max} := \min\left[2.2, 1.09 + \left(\frac{q_{c1Ncs}}{180}\right)^3\right]$$

$MSF_{max} = 1.444$

Supporting parameter for magnitude scaling factor. K568 (Hidden

$$MSF := 1 + \left(MSF_{max} - 1\right) \cdot \left(8.64 \cdot \exp\left(\frac{-M_w}{4}\right) - 1.325\right)$$

$MSF = 0.957$

Magnitude scaling factor at the sample of interest. L568

$$CRR := CRR_{7.5} \cdot MSF \cdot K_\sigma \cdot K_\alpha$$

$CRR = 0.173$

Corrected cyclic resistance ratio at the sample of interest. M568

$$\alpha_z := -1.012 - 1.126 \cdot \sin\left[\left(\frac{D_{sample} + El_{FinalGrade} - El_{TOH}}{11.73m}\right) + 5.133\right]$$

$\alpha_z = -1.723$

Supporting parameter for the stress reduction coefficient. N568

$$\beta_z := .106 + .118 \cdot \sin\left[\left(\frac{D_{sample} + El_{FinalGrade} - El_{TOH}}{11.28m}\right) + 5.142\right]$$

$\beta_z = 0.188$

Supporting parameter for the stress reduction coefficient. O568

$$r_d := \min\left(1, \exp\left(\alpha_z + \beta_z \cdot M_w\right)\right)$$

$r_d = 0.772$

Stress reduction coefficient at the sample of interest. P568

$$CSR := 0.65 \cdot \left(\frac{\sigma_{v,sample,EQ}}{\sigma'_{v,sample,EQ}}\right) \cdot \left(\frac{a_{max}}{g}\right) \cdot r_d$$

$CSR = 0.345$

Cyclic stress ratio at the sample of interest. W568

$Screen_{clay\text{-}like} := if(n = 1.0, "TRUE", "FALSE")$

$Screen_{clay\text{-}like} = "FALSE"$ Boolean to determine if sample has been classified as clay-like or sand-like. If sample is clay-like, it is screened out from liquefaction. X568

$Screen_{HighTipRes} := if(q_{c1Ncs} \geq 175, "TRUE", "FALSE")$

$Screen_{HighTipRes} = "FALSE"$ Boolean to determine if sample has a sufficiently high clear sand equivalent blow count. If qc1Ncs exceeds 175, the sample is screened out from liquefaction. Y568

$Screen_{unsat} := if(D_{H20,EQ} > D_{sample}, "TRUE", "FALSE")$

$Screen_{unsat} = "FALSE"$ Boolean to determine if sample is unsaturated. Unsaturated samples are screened out from liquefaction. Z568

$$FS_{liq} := \begin{cases} "N/A" & \text{if } Screen_{unsat} = "TRUE" \\ "N/A" & \text{if } Screen_{HighTipRes} = "TRUE" \\ "N/A" & \text{if } Screen_{clay\text{-}like} = "TRUE" \\ round\left[\left(\frac{CRR}{CSR}\right), 1\right] & \text{otherwise} \end{cases}$$

Factor of safety against liquefaction calculation. Factor of safety is not calculated if the material was screened out. Additionally, the value is rounded to the nearest tenth. AA568

$FS_{liq} = 0.5$

LEGEND

For cases where the reasonable low, selected, and reasonable high values are within the valid range:

- Predicted residual strength at reasonable high value
- Predicted residual strength at selected value
- Predicted residual strength at reasonable low value

For cases where some value(s) is(are) not within the valid range:

- Reasonable high value outside valid range; upper bound shown as max. value within valid range.
- Predicted residual strength at selected value
- Predicted residual strength at reasonable low value
- Reasonable high and selected value outside valid range; upper bound shown as maximum value within valid range.
- Predicted residual strength at reasonable low value
- Reasonable high, selected, and reasonable low value outside valid range; line shown is maximum value within valid range.

Selected Value:

- Selected value, Sus = 200 psf

*Sus values are calculated from empirical c/p values for these methods. The selected, representative effective stress was 0.6 tsf.

APPENDIX E – A REFERENCE FOR CHARACTERIZING THE ENGINEERING PROPERTIES OF SOILS

A Reference for Characterizing the Engineering Properties of Soils

Purpose:

- This document provides focused background discussion, typical values, empirical correlations, and guidance for selecting engineering soil properties.

A Reference for Characterizing the Engineering Properties of Soils

1. Introduction

This document provides focused background discussion, typical values, empirical correlations, and guidance for selecting engineering soil properties. The emphasis is on the soil parameters needed for slope stability analyses. The measurement and selection of soil properties is a broad subject, and this document does not provide a comprehensive review. Good textbook treatments are provided in Lambe and Whitman (1969), Holtz and Kovacs (1981), Terzaghi et al. (1996), and Duncan et al. (2014).

It is impossible to anticipate the conditions that will be encountered at a particular site or project. The engineering team must select the appropriate methods for characterizing each soil, based on the available data, specific characteristics of the material, geologic setting, application of the parameter in the analysis, and professional judgment.

2. Density Parameters

The unit weight of a given soil varies with water content, with different values in a deposit above or below the water table. Unit weights for various moisture conditions can be computed as follows:

Dry unit weight $$\gamma_d = \frac{G_s}{1+e}\,\gamma_w$$ **Equation 1**

Moist unit weight $$\gamma_m = \gamma_d(1+w)$$ **Equation 2**

Saturated unit weight $$\gamma_{sat} = \frac{G_s + e}{1+e}\,\gamma_w$$ **Equation 3**

where G_s is the specific gravity of the solids, e is the void ratio, w is the gravimetric moisture content, and γ_w is the unit weight of water (62.4 pcf). Specific gravity is typically about 2.65 for sands, and about 2.7 for clays.

The gravimetric water content (w) is the ratio of the water weight over dry weight of solids in the soil. The volumetric water content (θ), defined as the ratio of water volume over total soil volume, is used in some analyses. These two measures of moisture content can be related:

$$\theta = \frac{G_s\, w}{1+e} = \frac{S\, e}{1+e} = S\, n$$ **Equation 4**

where e is void ratio, S is saturation, and n is porosity. In a saturated soil (S = 100%), the volumetric water content is equal to the porosity.

Direct measurements of density properties are obtained from field and laboratory testing. When direct measurements are not available, these properties can be estimated using typical values for similar materials, such as those tabulated in Figure 1 through Figure 3. In granular soils, unit weights can be estimated based on penetration resistance, which can be correlated to relative density (see Figure 19).

Notes:

1. All properties are for condition of "Standard Proctor" maximum density, except values of k and CBR which are for "modified Proctor" maximum density.
2. Typical stength characteristics are for effective strength envelopes and are obtained from USBR data.
3. Compression values are for vertical loading with complete lateral confinement.
4. (>) indicates that typical property is greater than the value shown.
   (..) indicates insufficient data available for an estimate.

3. Hydraulic Conductivity

This discussion relates to the seepage of water through soil per Darcy's law, wherein the seepage flow rate is proportional to the hydraulic gradient. The key soil parameter is the hydraulic conductivity (k); here, the generic term "permeability" is assumed to be synonymous with hydraulic conductivity.

Hydraulic conductivity varies over an extremely wide range for different soils, and the permeability of a large soil mass is difficult to determine with precision. Measurements made with discrete soil samples will fail to capture the influence of macro seepage features (fissures, discontinuities, inclusions, thin beds of different material, etc.) that may have a major impact on seepage through the soil mass. More representative values can sometimes be obtained through field testing, but such tests are expensive and difficult to interpret. The characterization of soil permeability parameters requires significant engineering judgment.

Seepage analyses may be performed to characterize the distribution of pore water pressures in an earth slope, without regard to seepage flow rates. For this type of problem, the relative permeabilities between the various soil strata and/or the ratio of horizontal to vertical permeability (anisotropy ratio) within a given soil zone, are more important to the model solution than the absolute permeability of any particular soil. Thinking about the flownet for a uniform, isotropic seepage problem, the head (or pressure) at any location is independent of the hydraulic conductivity. Also, if the permeability in one material is more than about two orders of magnitude higher than the adjacent soil, then the first will act like a drain and can be modeled as a boundary condition.

The engineer should consider these issues in selecting appropriate permeability parameters for a particular analysis, recognizing that the needed solution may not be sensitive to the permeability of some materials. Permeability estimates, based on typical values for similar soils, are often sufficient and appropriate for developing a reasonable seepage model. Testing and evaluation should be concentrated on the soil zones that are critical to the problem.

3.1. Saturated Soil Permeability

The tables and charts provided below are useful when estimating hydraulic conductivity for saturated soils, or when checking the validity of permeability measurements. The charts in Figure 4 classify soil behavior in terms of permeability ranges, while data for common soils and embankment materials are provided in Figure 3 and Figure 5 though Figure 7.

The hydraulic conductivity of clean, loose, uniform sands can be estimated using Hazen's empirical equation:

$$k \approx C\ (D_{10})^2 \qquad \textbf{Equation 5}$$

where k is the hydraulic conductivity (cm/sec), D_{10} (mm) is the effective grain size (10% of soil particles are smaller than D_{10}), and C is an empirical constant that typically varies between 0.8 and 1.2. This empirical correlation illustrates that permeability is strongly affected by the finer particles in a soil. However, Hazen's equation was developed for filter sands, and is thus limited in applicability to loose, uniform sands with less than 5% fines.

Hydraulic conductivity is also affected by how densely the soil particles are packed together. The change in permeability with the change in density, for a particular soil, can be estimated using:

$$k_1\left(\frac{e_2^3}{1+e_2}\right) = k_2\left(\frac{e_1^3}{1+e_1}\right) \qquad \textbf{Equation 6}$$

where k_1 is the permeability at a void ratio of e_1, and k_2 is the permeability of the same soil at a void ratio of e_2. Equation 6 is based on the Kozeny-Carman equation (Lambe and Whitman 1969).

In the laboratory, hydraulic conductivity can be measured directly from constant head permeability tests (preferred for soils with $k > 10^{-3}$ cm/sec) or falling head permeability tests (preferred for soils with $k < 10^{-5}$ cm/sec). The permeability of fine-grained soils can also be determined from the results of one-dimensional consolidation tests. The accuracy of laboratory permeability measurements is limited, in all cases, by how well the test specimen represents the in situ soil deposit.

In the field, hydraulic conductivity can be measured with borehole or well infiltration (slug) tests, with variations of constant head, falling head, and pumping. Large-scale aquifer pumping tests, with arrays of piezometer instrumentation, can also be used to characterize the permeability characteristics of large soil masses. Double ring infiltrometer tests are commonly used to measure vertical permeability on soil liners. Further discussion of all available test methods is beyond the scope of this document.

3.2. Permeability from Slug Tests

Hydraulic conductivity parameters can be determined from slug tests in screened wells or piezometers. In the field, water is either poured into or removed from the well, causing a nearly instantaneous increase or decrease in the water level. The water levels are then recorded at regular intervals until returning to the initial static level. The Bouwer-Rice solution is then fit to this data to estimate the saturated permeability, for horizontal seepage in the soil or rock strata surrounding the screened interval.

The Bouwer-Rice solution (Bouwer and Rice 1976; Bouwer 1989) for estimating the coefficient of saturated hydraulic conductivity assumes a volume of water is instantaneously removed from a well and the return of the water level is measured. The method is based on a solution of the Thiem equation for steady-state, radial water flow to a well (see Figure 8):

$$Q = 2\pi \cdot k \cdot L_e \frac{y}{\ln\left(\frac{R_e}{r_w}\right)}$$ **Equation 7**

where: Q = volumetric flow rate
k = coefficient of saturated hydraulic conductivity
L_e = length of open section of the well (screened interval)
y = vertical distance between water level in the well and static water level of groundwater aquifer
R_e = effective radial distance over which y is dissipated
r_w= radial distance of the undisturbed portion of the aquifer

The change in water elevation within a well over a change in time is:

$$\frac{dy}{dt} = \frac{-Q}{\pi r_c^2}$$ **Equation 8**

where r_c is the inside radius of the well casing if above the open portion of the well (the porosity of the surrounding material may need to be considered if the water level is changing in the open portion of the well)

Bouwer and Rice assumed that the draw-down of the water table around the well is negligible, flow in the vadose (unsaturated) zone can be ignored, head losses are negligible, and the aquifer is both homogeneous and isotropic. Bouwer and Rice combined the two equations and solved for the coefficient of saturated hydraulic conductivity assuming boundary conditions of y_o at t = 0.0 and y_t at t:

$$k = \frac{r_c^2 \cdot \ln\left(\frac{R_e}{r_w}\right)}{2 \cdot L} \cdot \frac{1}{t} \cdot \ln\frac{y_o}{y_t}$$ **Equation 9**

The effective radial distance over which y is dissipated (R_e) was determined by Bouwer and Rice for different geometries based on an electrical resistance network analog. Thus, the value must be determined from their literature (Bouwer and Rice, 1976). This form of the equation allows k to be calculated from the rise in water level after suddenly removing a slug of water from the well. The term $\frac{1}{t} \cdot \ln\frac{y_o}{y_t}$ may be determined from a best fit linear regression of field data plotted as ln(y) versus t.

Bouwer (1989) explained the applicability of using the method to determine the coefficient of saturated hydraulic conductivity from a slug test where water is added to the well.

3.3. Permeability from CPT Dissipation Tests

In situ soil permeability can be estimated from pore pressure dissipation data acquired during cone penetration testing (CPT). When the piezocone probe is stopped, at selected depths or intervals in a saturated deposit, the excess pore water pressures induced by pushing the cone will begin to dissipate. Based on consolidation theory, the rate of pore pressure dissipation can be related to the lateral hydraulic conductivity of the soil surrounding the probe. The method presented below assumes the penetration pore pressures are measured immediately behind the conical tip, at the "u_2" location.

The horizontal permeability (k_h) of a soil is determined from a CPT dissipation test as follows:

(1) Halt advancement of the piezocone and record the soil water pore pressures (u_t) as a function of time (t).

(2) From the data, determine the initial pore pressure (u_i) measured when the piezocone was halted, at t = 0.0.

(3) Estimate the static pore pressure (u_o) at the test location before penetration of the cone. This may be determined from knowledge of the ground water table in relation to the depth of the CPT probe, piezometric readings, or data from piezocone tests in adjacent sand layers.

(4) Compute the normalized excess pore pressure (U) for each measurement of u_t:

$$U = \frac{u_t - u_o}{u_i - u_o} \qquad \textbf{Equation 10}$$

(5) Plot the normalized excess pore pressure dissipation as a function of time, using a log scale for the time axis.

(6) From the plot of data, determine the measured time for 50% pore pressure dissipation (t_{50}, measured at U = 0.5).

(7) Alternatively, t_{50} may be determined from a square root of time plot, using the graphical construction technique commonly used to interpret soil consolidation test data.

(8) The coefficient of saturated, horizontal hydraulic conductivity can then be estimated using either of the charts in Figure 9 (note the difference in time units between the two charts).

The resulting estimates of soil permeability are only approximate and subject to significant uncertainty (Lunne et al. 1997).

3.4. Anisotropic Permeability

Most natural soils and embankment materials are anisotropic, typically with horizontal stratification due to horizontal bedding in natural deposits or the construction of fills in horizontal lifts. This usually results in a horizontal permeability (k_h) greater than the vertical permeability (k_v). Anisotropic permeability is characterized with the ratio of k_h/k_v (Note: SEEP/W uses the inverse ratio of k_v/k_h).

The magnitude of k_h/k_v is an important parameter to consider in a seepage analysis, but can be difficult to characterize. Vertical permeability is usually measured in laboratory tests, consistent with the orientation of borehole samples. Laboratory testing is less effective for measuring horizontal permeability, due to the difficulty of obtaining representative samples suitable for such tests. Field tests, including slug tests in screened wells (Section 3.2) and CPT dissipation tests (Section 3.3), induce mostly radial seepage; horizontal permeability is inferred, but some vertical seepage will occur. There are limitations associated with each of these measurements. The anisotropy of the materials is not measured directly, thus, the value of k_h/k_v must be approximated by combining different test results and considering knowledge of the subsurface stratigraphy.

The U.S. Army Corps of Engineers suggests that values of $k_h/k_v = 1, 10, 25, 100$ should be considered for parametric evaluations of underseepage (EM 1110-2-1901, USACE 1986). Typical ranges of k_h/k_v for various natural soils and embankment fills, as suggested by the U.S. Bureau of Reclamation (USBR 2011b), are listed in Figure 6 and Figure 7.

Selection of an appropriate value of k_h/k_v should consider the depositional environment for the material. Wind-blown soils (dune sands, loess) are relatively uniform, with k_h/k_v values in the range of 0.2 to 2. Residual soils may also have low k_h/k_v, depending on the structure of the parent rock. Deposition in water (alluvial, fluvial, and lacustrine environments) usually leads to highly stratified and variable soil deposits, with relatively high k_h/k_v. These classes of soils may have $k_h/k_v > 100$ (USBR 2011b). Anisotropy in bedrock is generally controlled by the degree of stratification and jointing.

The USBR (2011b) indicates that compacted embankment soils typically have k_h/k_v ratios in the range of 2 to 10. Older dams (built in early 20th century) and hydraulic fill dams may have k_h/k_v up to 50, due to older construction procedures that did not adequately scarify and mix the surface of each compacted soil lift. Coarse grained embankment zones, including drains, filters, and rockfill shells, can be assumed to have $k_h/k_v = 1$.

Degree of Permeability	Hydraulic Conductivity (cm/sec)
High	Greater than 10^{-1}
Medium	10^{-1} to 10^{-3}
Low	10^{-3} to 10^{-5}
Very Low	10^{-5} to 10^{-7}
Practically Impermeable	Less than 10^{-7}

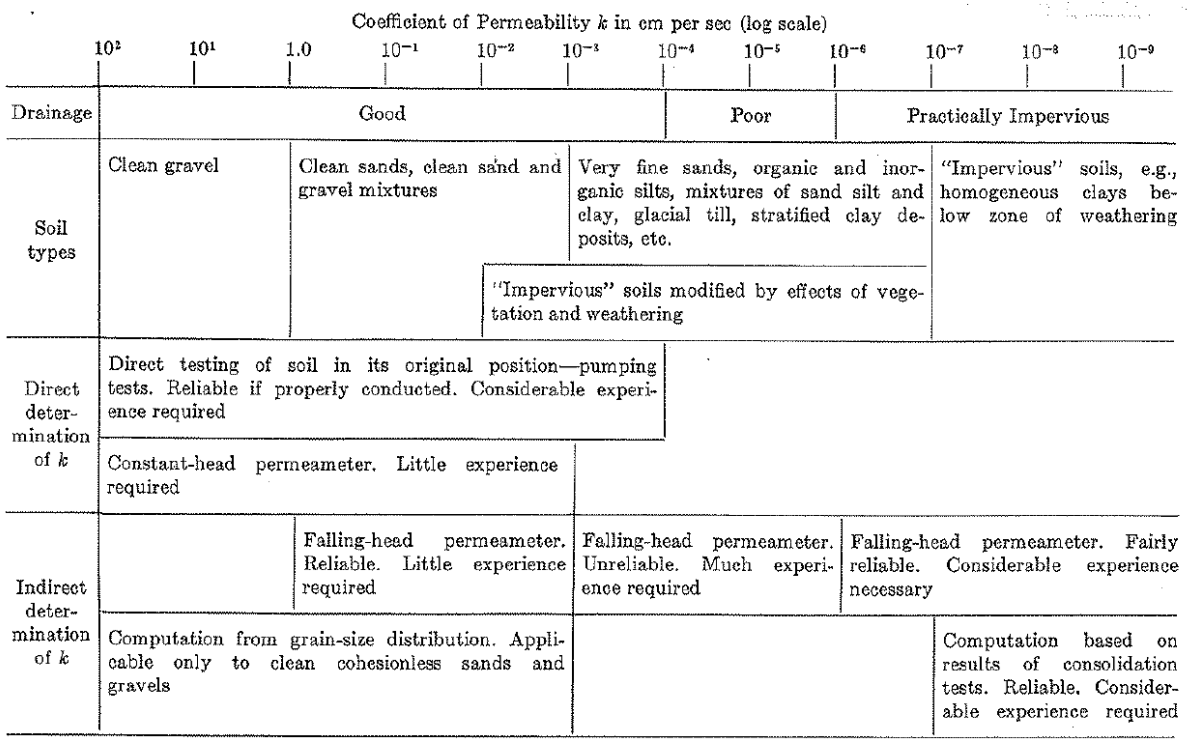

Figure 4. Hydraulic conductivity and classification of soils (from Terzaghi and Peck 1967).

Formation	Value of k (cm/sec)
River deposits	
Rhone at Genissiat	Up to 0.40
Small streams, eastern Alps	0.02–0.16
Missouri	0.02–0.20
Mississippi	0.02–0.12

3.5. Seepage in Unsaturated Soils

For unconfined seepage through an embankment, SEEP/W locates the phreatic line or water table (where the pressure head is zero) using an iterative process (GEO-SLOPE

2010). To find a rational solution, the software models the reduction in hydraulic conductivity with decreasing degrees of saturation (increasing matric suction) using the soil-water characteristic curve and hydraulic conductivity function described here.

These models are defined in terms of the *volumetric* water content (θ), which is related to the gravimetric water content (w) per Equation 4. Suction pore pressures are quantified in terms of the matric suction, which is the difference between the pore air pressure and the water pressure in an unsaturated soil (Fredlund and Rahardjo 1993).

3.5.1. Soil-Water Characteristic Curve

The Soil-Water Characteristic Curve (SWCC) represents the amount of water within the soil structure at various applied suctions (Fredlund and Rahardjo 1993). Figure 10 shows a typical soil-water characteristic curve, also known as a volumetric water content curve, plotted over a range of pore water pressure (negative to positive). Soils exhibit hysteresis in this relationship for wetting and drying, but only the SWCC curve for drainage (desorption) is discussed here. The SWCC is characterized by four parameters: the air entry pressure (described using a curve-fitting parameter α), the slope of the function for changes in pore water pressure (described using a curve-fitting parameter n), the residual volumetric water content (θ_r), and the saturated volumetric moisture content (θ_s).

The air entry value (AEV), represents the matric suction pressure where a saturated soil begins to de-saturate (where air enters the pores). At pore pressures above the AEV, the water within the soil mass can be removed by compressing the sample; therefore, the slope of the curve under positive pore pressures is equal to the coefficient of volume compressibility (M_v) for one-dimensional consolidation (GEO-SLOPE 2010). Once the pore water pressure falls below the AEV, water cannot be compressed out of the sample; rather, water can only be removed from the voids by applying suction pressure. Therefore, the SWCC for pressures below the AEV indicates how much water can be removed as the matric suction is increased, until the residual water content is reached. The residual volumetric water content (θ_r) occurs where further increases in matric suction do not result in significant changes in water content (Fredlund and Rahardjo 1993). The saturated volumetric moisture content (θ_s), defines the intersection of the SWCC and the x-axis (i.e. pore water pressure equals zero).

Within SEEP/W, the user can define the SWCC using direct measurements from laboratory tests, the built-in library of curves based on material classification, or one of the models proposed by Aubertin at al. (2003), van Genuchten (1980), and Fredlund and Xing (1994).

When available, laboratory test data should be used to define the soil-water characteristic curve in the SEEP/W model. Five standardized test methods, which vary in applicability based on fines content and pressure ranges, are presented in ASTM D6836. Method C, for finer soils and intermediate suctions (100 to 1000 kPa), can be used for most soil samples. When using laboratory data, it may be necessary to augment the data for the higher and lower suction pressures not tested. The Aubertin,

van Genuchten, or SEEP/W soil type models can be used to develop a standard curve shape, which can then be modified to fit the available laboratory data.

In the absence of laboratory testing, the following methods can be used to develop the SWCC:

- The "Modified Kovacs" method (Aubertin et al. 2003) develops the curve using standard laboratory test data such as grain size distribution, Atterberg limits (if applicable), and the saturated volumetric water content.

- SWCC parameters can be estimated from empirical relationships using soil index properties or using typical published values. Figure 11 provides some tables of typical values. Typical van Genuchten model parameters (α, n) including residual (θ_r) and saturated (θ_s) water contents are compiled from the UNSODA database (Leij et al., 1996). N indicates the number of soils or samples of a given textural class from which the mean values are compiled. During desorption, large pores drain more freely than smaller pores. Materials with larger particles and larger pores (e.g., sand and gravel) will retain less water under higher suction pressures. SWCC for coarse soils are difficult to measure in the laboratory. Figure 12 provides published values of curve fitting parameters for coarse soils and illustrates the corresponding SWCC.

- The SWCC can be approximated by choosing one of the functions developed by GEO-SLOPE for a given soil texture, which are based on functions taken from published literature (GEO-SLOPE 2010). The six available models are based on the soil type: Clay, Silty Clay, Silt, Silty Sand, Sand, and Gravel (shown in Figure 13). The models shown are for illustration purposes only and are dependent on the saturated volumetric water content.

3.5.2. Hydraulic Conductivity Function

When the soil is saturated, water flows through the pores easily, but as the water content decreases, the hydraulic conductivity drops rapidly as the water in the soil pores is no longer contiguous. Hence, the hydraulic conductivity of an unsaturated soil is dependent on the volumetric water content. SEEP/W estimates the hydraulic conductivity of unsaturated soils by using the SWCC, the suction pressure within the soil, and the saturated hydraulic conductivity of the soil.

A Hydraulic Conductivity Function can be derived to estimate the hydraulic conductivity over a range of suction pressures. The two methods available in SEEP/W to derive the Hydraulic Conductivity Function are from Fredlund and Xing (1994) and van Genuchten (1980). The saturated hydraulic conductivity (Section 3.1) and the SWCC are required to create the hydraulic conductivity curve. Figure 14 shows an example Hydraulic Conductivity Function for various saturated hydraulic conductivity values.

4. Small-Strain Shear Stiffness

4.1. Elastic Stiffness and Wave Velocity

In an elastic medium, the velocity of a stress wave is equal to the square root of the ratio of elastic modulus over mass density. For a shear wave, the velocity (V_s) is related to the shear modulus (G). The shear response of soils is nonlinear, such that the shear modulus declines at increasing shear strains (softening). The elastic response is limited to very small strains, where the shear modulus is maximum. Hence, the maximum shear modulus (G_{max}) in a soil at small strains is proportional to the square of the shear wave velocity in that soil:

$$G_{max} = \rho \, V_s^2 \qquad \textbf{Equation 11}$$

where ρ is the mass density (total unit weight divided by acceleration due to gravity, 32 ft/sec^2).

Shear wave velocities can be measured in multiple ways. Resonant column or cyclic triaxial testing can be used in the laboratory, but in situ field measurements are preferred. Field techniques include cross-hole testing in boreholes, down-hole testing during cone penetration tests, seismic refraction methods, and other surface and downhole geophysical methods. Direct, field measurements of shear wave velocity are the best method for characterizing the small-strain shear modulus of a soil mass.

When shear wave measurements are not available, G_{max} can be estimated using various empirical correlations. Such correlations have been published by Ishihara (1996) and Kramer (1996). A few select correlations are presented below.

4.2. G_{max} Correlations Based on Void Ratio

Seed and Idriss (1970) proposed this correlation for sand:

$$G_{max} = 1{,}000 \, K_{2,max} \, (\sigma'_m)^{0.5} \qquad \textbf{Equation 12}$$

where G_{max} is the small-strain shear modulus (psf) and σ'_m is the mean effective stress (psf). The correlation factor $K_{2,max}$ in Equation 12 is estimated based on the void ratio (e) or relative density (D_r) of the sand:

e	$K_{2,max}$	D_r (%)	$K_{2,max}$
0.4	70	30	34
0.5	60	40	40
0.6	51	45	43
0.7	44	60	52
0.8	39	75	59
0.9	34	90	70

Another relationship, more generally applicable to various soil types, was proposed by Hardin (1978):

$$\frac{G_{max}}{P_a} = \frac{625}{0.3 + 0.7\,e^2}\,OCR^k\left(\frac{\sigma'_m}{P_a}\right)^{0.5} \qquad \textbf{Equation 13}$$

where e is the void ratio and OCR is the overconsolidation ratio. P_a is one atmospheric pressure (101.3 kPa or 2,116 psf), in the same units as G_{max} and the mean effective stress (σ'_m). The exponent k in Equation 13 is related to plasticity index (PI), and can be interpolated between these values (Hardin and Drnevich 1972):

PI	k
0	0.00
20	0.18
40	0.30
60	0.41
80	0.48
≥ 100	0.50

In these correlations, the mean effective stress is defined as

$$\sigma'_m = \frac{1}{3}(\sigma'_1 + \sigma'_2 + \sigma'_3) \approx \frac{2}{3}\,\sigma'_v \qquad \textbf{Equation 14}$$

where σ'_1, σ'_2, and σ'_3 are the principal effective stresses. In most applications, assuming at-rest conditions and $K_o = 0.5$ will provide sufficient accuracy. The mean stress is then about two-thirds of the vertical effective stress, as indicated in Equation 14.

4.3. G_{max} Correlations Based on Penetration Resistance

The value of G_{max} may be estimated on the basis of correlations with in situ penetration resistance. For sand, Seed et al. (1986) suggest:

$$G_{max} = 20{,}000\,(N_1)_{60}^{0.333}\,(\sigma'_m)^{0.5} \qquad \textbf{Equation 15}$$

where G_{max} is the small-strain shear modulus (psf), σ'_m is the mean effective stress (psf), and $(N_1)_{60}$ is the normalized, corrected Standard Penetration Test (SPT) blowcount.

When cone penetration test (CPT) data is available, G_{max} in sands may be estimated using (Rix and Stokoe 1991):

$$G_{max} = 1{,}634\,(q_c)^{0.250}\,(\sigma'_v)^{0.375} \qquad \textbf{Equation 16}$$

where G_{max} is the small-strain shear modulus, q_c is the CPT tip resistance, and σ'_v is the vertical effective stress, all expressed in units of kPa. In clays, G_{max} may be estimated from CPT data using (Mayne and Rix 1993):

$$G_{max} = 406\,(q_c)^{0.695}\,(e)^{-1.130} \qquad \textbf{Equation 17}$$

G_{max} and σ'_v are expressed in units of kPa, and e is initial void ratio of the soil.

4.4. G_{max} Correlations Based on Site-Specific Data

Maximum shear modulus (G_{max}) typically varies with effective stress level and can be generally defined as follows:

$$G_{max} = G_o \left(\frac{\sigma'_m}{P_a}\right)^{0.5} \qquad \textbf{Equation 18}$$

Shear wave velocity measurements obtained from field or lab testing are often available over a limited range of effective stresses that may not encompass the range of stresses of interest in ground response analyses. In this scenario, site-specific data can be extrapolated to a broader stress range by selecting a representative G_o value for a given material. The representative G_o value should be selected such that shear wave velocities calculated using Equation 18 and Equation 11 match field or lab measurements reasonably well over the stress range where data is available. In effect, this creates a site-specific empirical correlation. An example correlation and the associated field data are shown in Figure 15.

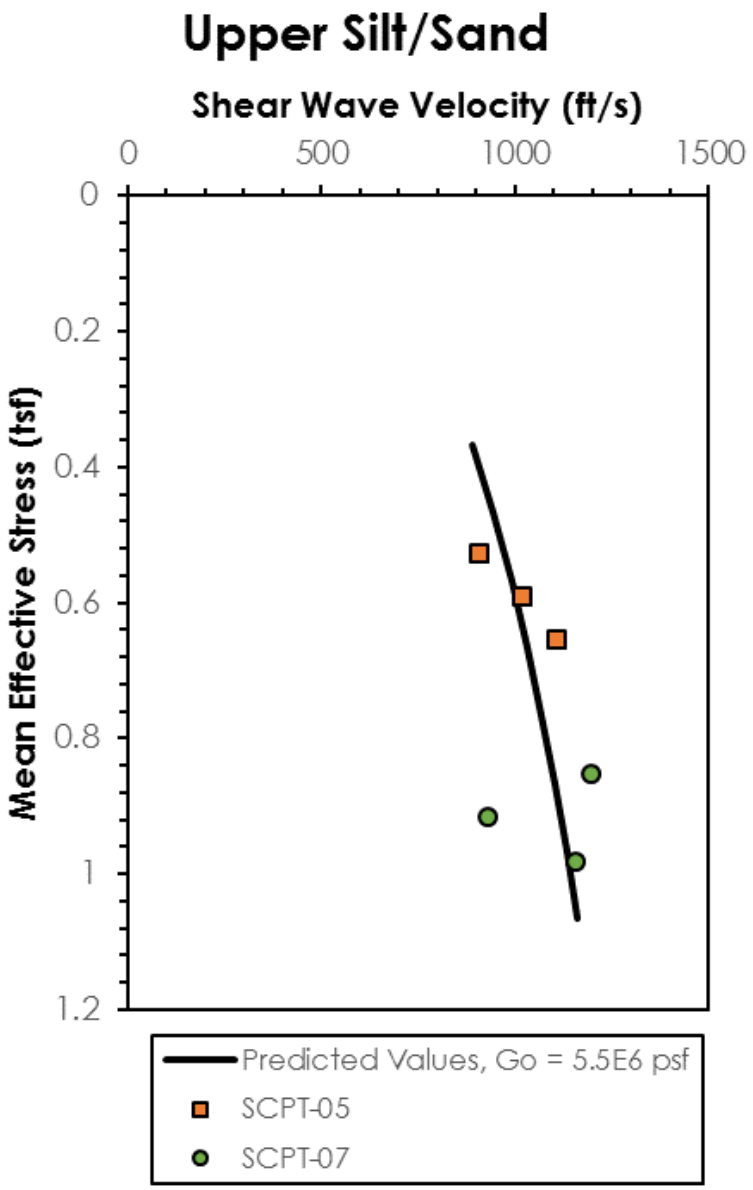

Figure 15. Example site-specific empirical correlation for shear wave velocity

5. Strength Parameters from Laboratory Test Data

Soil strengths can be determined from the results of laboratory tests, including direct shear, triaxial compression, triaxial extension, and direct simple shear tests. From the measured soil response to loading, the "failure" stresses are plotted and a Mohr-Coulomb failure envelope is fit to the data. In geotechnical engineering practice, soil shear strengths (S) are commonly characterized in terms of the intercept (c) and slope (tan ϕ) of the Mohr-Coulomb envelope:

$$S = c + \sigma \tan\phi \qquad \textbf{Equation 19}$$

5.1. Definition of Failure

Selecting the point of failure in a laboratory test record requires some engineering judgment. Criteria that are commonly used to define "failure" include:

- The point of maximum or peak applied shear stress.
- The shearing resistance at some arbitrary, limiting strain level (usually 15% axial strain in triaxial compression).
- The maximum principal effective stress ratio (maximum value of σ'_1/σ'_3); sometimes identified as the point of maximum obliquity, this stress condition is one where the slope of a failure envelope through the origin of stress has a maximum slope (maximum ϕ for c = 0).
- The residual shearing resistance at large strain.

When selecting the point of failure in a particular test, the following guidelines should be followed:

- When considering data from drained (CD) tests, failure can be defined as the point of maximum shear stress or 15% axial strain, whichever occurs first. In a drained triaxial test, the maximum value of σ'_1/σ'_3 occurs at the point of maximum applied shear stress, so both criteria will give the same result.

- In evaluating effective stress parameters (c' and ϕ') from CU test data, failure should be assumed at the maximum principal effective stress ratio.

- When analyzing data from undrained (UU or CU) laboratory tests, the peak axial stress should be assumed to represent failure when determining undrained strength parameters (c and ϕ). If the test data does not exhibit a peak stress prior to 15% axial strain (for triaxial testing), then the stresses at 15% strain should be used as failure.

Note that the drained and undrained failure stresses will occur at different points in a given CU test, due to the different definitions of failure used in each case.

5.2. Fitting Strength Envelopes

Values of c and ϕ are determined from a straight line, tangent envelope fit to Mohr's circles representing failure stresses. When working with data from multiple laboratory tests, fitting of the failure envelope may be facilitated by plotting the failure points on a "p-q plot", where:

$$p = \frac{\sigma_1 + \sigma_3}{2} \qquad \textbf{Equation 20}$$

$$q = \frac{\sigma_1 - \sigma_3}{2} \qquad \textbf{Equation 21}$$

A "best-fit" line through the p-q failure points (identified as the K_f line) will then have an intercept of "d" and a slope of "tan a". Equivalent Mohr-Coulomb parameters can then be computed as:

$$\sin\phi = \tan\alpha \qquad \textbf{Equation 22}$$

$$c = \frac{d}{\cos\phi} \qquad \textbf{Equation 23}$$

Equation 20 through Equation 23 can be used with either drained strengths (c' and ϕ') or undrained strengths (c_R and ϕ_R for R-envelopes).

Note that the Mohr-Coulomb failure model (Equation 19) corresponds to a linear increase in shearing resistance with higher normal stress. Actual failure envelopes for soils are curved, with significant curvature in the effective stress envelopes for granular soils over large pressure ranges and for overconsolidated clays. In practice, values of c and ϕ are determined for soils from straight line envelopes fit to specific ranges of stress.

In fitting strength parameters to multiple test results, the practice of the U.S. Army Corps of Engineers is to select design values of c' and ϕ' (or c and ϕ) so that data from about two-thirds of the tests are above the failure envelope (USACE 2003). This guidance can also be used in selecting design values of undrained shear strength (S_U) or c/p ratios; that is, about two-thirds of the measured strengths should be above the strength used in design.

6. Drained Strength Parameters for Static, Long Term Conditions

6.1. Basis

Excess (or deficient) pore water pressures, generated by changes in mean stress or shearing stress, will dissipate under static, long term conditions. Pore pressures within a soil can then be computed assuming hydrostatic conditions or from a solution for steady state seepage. As long as the distribution of pore pressure within the cross section can be quantified, effective stresses can be computed and the drained shear strength (S_d) of the soils can be determined from effective stress strength parameters (c' and ϕ'):

$$S_d = c' + \sigma' \tan \phi' \qquad \textbf{Equation 24}$$

6.2. Effective Stress Cohesion Intercept

Uncemented, granular soils exhibit no strength at zero effective stress ($\sigma' = 0$), corresponding to c' = 0. Over a wide pressure range, granular soils have a curved strength envelope. Fitting a straight line through segments of a curved failure envelope can result in c' > 0, but these values are applicable only for modeling the shear strength over the specified range of effective stress. In the case of unsaturated soils with fines, suction creates an apparent cohesion, but this component of strength is lost when the soil becomes saturated. In general, zero cohesion (c' = 0) should be assumed for uncemented, granular soils.

Normally consolidated, saturated clays also have no shear strength at zero effective stress. The drained, Mohr-Coulomb failure envelope for the peak strength of a normally consolidated clay will have c' = 0.

The peak strength envelope for an overconsolidated clay will exhibit drained cohesion. Below the effective preconsolidation pressure, the drained strength envelope for an overconsolidated clay is above the envelope for the normally consolidated condition. The overconsolidated, peak strength envelope is nonlinear, and curves toward the origin at very small effective stresses (Figure 16). Linear Mohr-Coulomb failure parameters (with c' > 0) can be fit to the curved strength envelope for overconsolidated soils; however, envelopes fit with c' > 0 will tend to overestimate the drained shearing resistance at shallow depths.

Moderately to heavily overconsolidated clays in the field are often fissured, especially at shallow depths. Because test specimens tend to be taken between the fissures, laboratory tests on smaller specimens tend to yield larger values of c', compared to tests on larger samples of such soils. For overconsolidated soils, c' determined from laboratory testing thus tends to be larger than the in situ cohesion of the soil mass, and thus potentially unconservative. In addition, cycles of shrinking (drying) and swelling (wetting) lead to softening and a loss of stress history over time along the fissures. Fully softened strengths (Section 6.3) with c' = 0 (Stark et al. 2005) are thus appropriate for characterizing the drained strength of stiff, fissured, overconsolidated clayey soils.

Fell et al. (2005) point out that measured values of drained cohesion may be adversely affected by potential shortcomings in the laboratory test results. For example, if tests are run at confining stresses higher than experienced in the field, a straight line fit through that data may overpredict the drained strength at lower effective stresses. If the soil sample is not completely saturated, or if the strain rate is too high to allow equilibration of pore pressures within the sample during the test, then the pore pressure data will not accurately reflect the pore pressures at failure. This will tend to shift the Mohr's failure stress circles, which can result in a misleading indication of drained cohesion.

At very large shear strains, clay particles will align with the slip surface and a residual shearing resistance is realized. Drained, residual strength envelopes (Figure 16) are independent of overconsolidation and have no cohesion (c' = 0). Residual strength parameters should be used when evaluating stability where sliding has previously occurred.

In the absence of particle cementation/bonding, long term (drained) shearing resistance related to c' > 0 may be unreliable. In routine geotechnical design practice, values of c' = 0 are usually assumed for both normally and overconsolidated saturated clays, and for uncemented granular soils. In the evaluation of long-term stability, Stark et al. (2005) recommend using zero effective stress cohesion (c' = 0) for soft to stiff clays, unless back-analysis of local case histories support a greater value. However, this recommendation considers the potential for softening of stiff clays, and may not apply to full depth (See Section 6.3).

Detailed testing and characterization of a particular soil, coupled with careful application of the fitted strength envelopes, are necessary where values of c' are used in a stability evaluation. Fell et al. (2005) recommend that design values of c' for peak strength should not exceed about 200 psf (or 20 psf for residual strengths) without definitive evidence for higher values.

When surficial soils have c' = 0, shallow sliding parallel to the ground surface will be the critical failure mechanism (lowest factor of safety) found in a slope stability analysis. This mode of failure, which might require periodic regrading and maintenance, is often considered to be less critical in a stability analysis.

Specific guidance on the selection of c' values is provided in Section 6.7.

6.3. Fully Softened Strengths of Overconsolidated Clays

In excavations and embankments, long-term failures may develop in overconsolidated clays at shear stresses below the peak drained strength. Seasonal moisture changes near the ground surface, or lateral stress relief in deep excavations, will cause fissures to open, swelling of the soil along the fissures, and the gradual loss of the beneficial effects of overconsolidation. Over time (years to decades), the peak strength of the overconsolidated soil mass may degrade to the lower strength of the soil when normally consolidated (Skempton 1970). "Fully softened strengths" (Figure 16) are appropriate for characterizing the drained strength of such soils. The understanding of this behavior, and the appropriate application of this concept for

design, is an evolving area within geotechnical engineering. Duncan et al. (2011) and VandenBerge et al. (2013) provide an overview of current geotechnical engineering practice, based on the outcomes of a 2011 industry workshop.

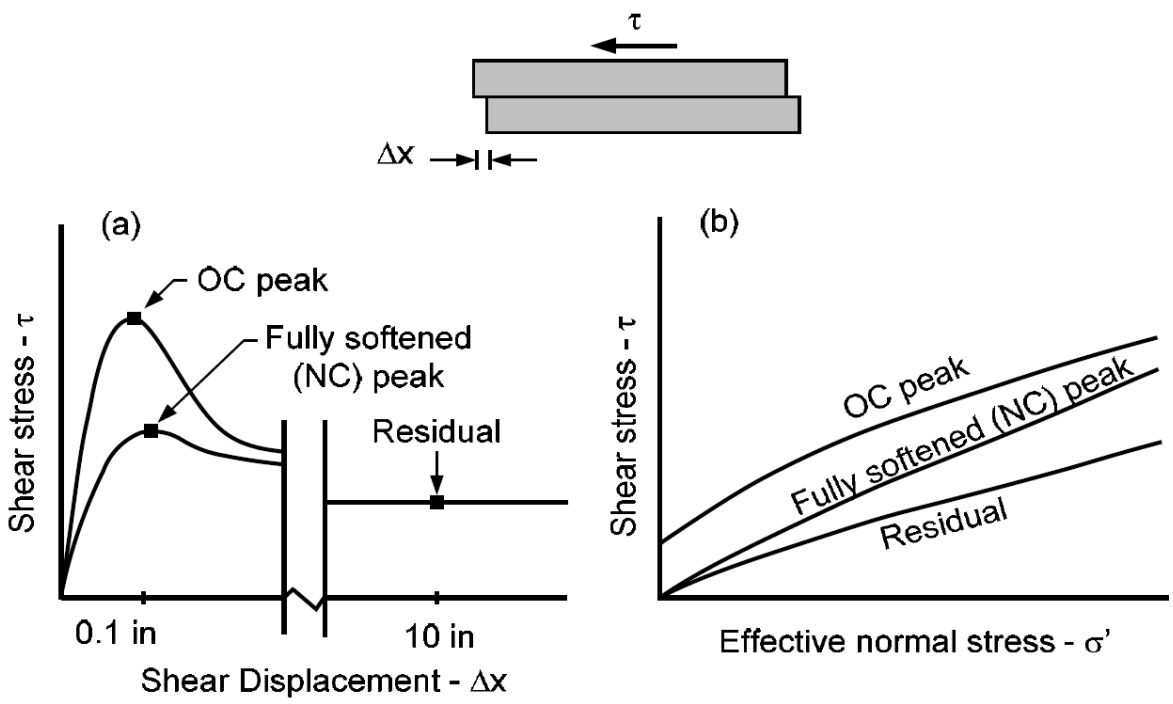

Figure 16. (a) Stress-displacement curves for overconsolidated and fully softened (normally consolidated) natural stiff fissured clays, and (b) overconsolidated peak, fully softened peak and residual strength envelopes (from VandenBerge et al. 2013).

The softening behavior, under drained long-term conditions, may occur in any clayey soil, but is most pronounced in highly plastic clays. The need to consider fully softened, drained strengths is greater in soils with higher plasticity index, the existence of fissures or shrinkage cracks, water contents above the shrinkage limit, higher clay fractions, lower silt or sand content, and higher activity (Duncan et al. 2011; VandenBerge et al. 2013). Long-term instability due to softening should be considered for (1) excavations in stiff fissured clays, where the stress relief caused by the excavation can lead to swelling, and (2) shallow sliding in compacted clay embankments, due to the formation of desiccation cracks from seasonal wetting-drying and freeze-thaw.

Fully softened strengths may be measured in triaxial or ring shear tests, but direct shear tests are preferred (Duncan et al. 2011; VandenBerge et al. 2013). Tests are conducted on remolded, normally consolidated samples that are initially mixed to water contents near the liquid limit, then consolidated back to void ratios matching the field conditions. Peak shear stresses from tests on the remolded samples are used to define the fully softened strength envelope, which should be the same as the drained, peak

strength of the soil when it is normally consolidated (Skempton 1970). When test data are unavailable, the fully softened strength can be approximated by using estimated, drained strength parameters (with c' = 0) for the soil in a normally consolidated condition.

In overconsolidated clays, the fully softened strength envelope is intermediate between the peak and residual drained strength envelopes (Figure 16). The fully softened strength envelope is curved, with essentially no cohesion (c' = 0 at σ' = 0). Hence, when using Mohr-Coulomb parameters for a linear fit, an envelope with c' > 0 will overestimate strengths at very low stress levels (shallow depths). Using an envelope with c' = 0 is conservative, but may be overly conservative when applied to soils at greater depths (higher stress ranges). An alternative is to model the nonlinear strength envelope, using secant friction angles, in the stability analysis (Stark et al. 2005).

In a slope, shear stresses along a potential failure surface are not uniform, and overstressed areas that lose shearing resistance past the peak strength will cause increasing shear stresses on other parts of the slip surface. This can lead to a progressive failure over time. The use of fully softened strengths in design, instead of relying upon the peak strength in strain softening soils, helps to avoid progressive failures (Skempton 1970).

When looking at the stress-strain test data, it is important to note if the laboratory tests were drained or undrained. Stiff, moderately to heavily overconsolidated clays usually exhibit significant strain softening behavior in drained shear. These soils are dilative, resulting in a loss of shearing resistance with localized expansion along the failure surface. Most laboratory tests on clayey soils are conducted using consolidated-undrained conditions. When dilative soils are subjected to undrained testing, a strain hardening behavior will be observed, because the dilative response will cause decreasing pore pressures and increasing effective stresses. Hence, strain hardening in undrained shear is an indicator of expected strain softening under long-term, drained shear.

Fully softened strengths are an important consideration when evaluating the stability of compacted embankments constructed of highly plastic soils. However, it is overly conservative to assume fully softened strengths throughout the full depth of an overconsolidated clay (Duncan et al. 2011; VandenBerge et al. 2013). One exception may be where an embankment is built over an earlier embankment, or foundation soil, that previously experienced softening.

The depth of softening is related to the depth of the excavation, the depth of seasonal moisture change, and/or the depth of desiccation cracking. The appropriate depth will depend on the characteristics of the soil, the climate at the site, and the geologic history. For embankments, the depth of softening may be limited to 2 to 3 meters at most sites, and up to 4 meters in some cases (Duncan et al. 2011; VandenBerge et al. 2013). Lesser depths of softening may be expected in regions without extreme wet and dry seasonal climates.

6.4. Depth of Surficial Softening

A compacted soil near the surface of an embankment may lose some of its drained shear strength (soften) over time. Softening in overconsolidated, fine-grained soils is associated with shrink and swell, due to seasonal variations in moisture content at shallow depths, and freeze-thaw. The development of fully softened strengths is discussed in Section 6.3.

For TVA dams, fully softened strengths are assumed to apply only in highly plastic CH or MH soils having a plasticity index greater than 40 (fine grained soils with LL > 50 and PI > 40). In these soils, the depth of softening is assumed to be 5 feet (measured normal to the ground surface). No softening is assumed on armored slopes that are covered with stone riprap.

6.5. Laboratory and Field Measurement

In the laboratory, values of c' and ϕ' can be measured in consolidated drained (CD) tests, or consolidated undrained (CU) tests with pore pressure measurements. CD tests are preferred, but CU tests are usually specified for low permeability soils where the time required for drained testing becomes excessively long. Effective stress failure envelopes measured with CU tests are typically close to those measured in CD tests, and the two test methods are usually assumed to give equivalent values of c' and ϕ'.

Triaxial compression tests are commonly specified for both CD and CU tests. Consolidated-drained tests can also be run in a direct shear apparatus, which is a valid option for measuring the drained strength of low permeability clays. Because relatively thin samples can be tested in direct shear, the time required for consolidation and loading to failure will be much less than in drained triaxial tests. Direct shear tests force failure along a horizontal plane, which may not be the weakest plane in an anisotropic soil, but can be used to measure the shearing resistance along carefully aligned bedding planes. Direct shear tests, especially those conducted using ring-shear devices, are particularly useful for measuring residual strengths at large shear displacements. These considerations can be usually neglected when coarse grained soils are tested in direct shear.

Effective stress parameters can also be estimated using empirical correlations with in situ penetration resistance. Correlations between ϕ' and Standard Penetration Test (SPT) blowcounts in sands are presented in Figure 17. Correlations with Cone Penetration Test (CPT) tip resistance are given in Figure 18.

6.6. Typical Values

Typical values of drained friction angles (ϕ') for sands and clays are given, respectively, in Figure 19 and Figure 20. Typical drained strengths in compacted soils are listed in Figure 3. These typical values are helpful in judging the veracity of results from laboratory tests or in situ penetration tests. Note that there is significant scatter in these correlations, particularly for the clay strengths in Figure 20.

Estimated strength parameters, estimated on the basis of these typical values, are sometimes used for non-critical soil materials in a stability analysis. However, where the strength parameters assigned to a soil layer are critical to the computed stability of the slope, those values should be backed up by testing.

6.7. Recommended Practice

Natural deposits of granular soils are often highly variable, as a result of their geologic history and means of deposition. Laboratory tests on a few discrete samples from such a deposit are valuable, but may not yield a complete understanding of the variability in shearing resistance in that deposit. Correlations to in situ, field penetration tests (SPT or CPT) may be preferred for characterizing the drained strength of a granular soil deposit, because one can consider many more data points and better understand variability across the deposit. The reasonableness of the results should be checked by comparison to typical values for similar soils, and may be verified with laboratory testing.

Significant variability may also be encountered in clayey soils, particularly in residual soils. However, whether formed in place by weathering or deposited in water, clay soils tend to be more uniform than granular soil deposits. Laboratory testing of field samples will give a useful measure of drained strength parameters for such soils. Consolidated undrained (CU) tests, with the measurement of pore water pressures, can be used to obtain drained, effective stress strength parameters.

In many (but not all) design problems involving fine grained or clay soils, the short term, undrained conditions will govern stability. In those cases, attention should focus on the accurate assessment of undrained strengths, and reasonable estimates of drained strength parameters based on published, typical values may be sufficient for checking long-term stability. In other design problems, long-term, drained conditions may govern, and careful attention must be given to the selection of appropriate effective stress strength parameters.

When determining drained strength parameters, the following practice is recommended:

(1) A cohesion intercept may be appropriate for cemented soils, as long as the cementation is permanent, and not apparent cohesion due to matric suction in an unsaturated soil.

(2) Values of $c' > 0$ may be used to represent segments of curved strength envelopes over specified pressure ranges.

(3) When fitting envelopes through scattered test data, a line forced through $c' = 0$ should be considered first (as opposed to mathematical regression fits). If a good fit to the data is obtained, then the values of $c' = 0$ and ϕ' from that fit should be used.

(4) Values of c' > 0 may be used, but only if supported by adequate test data. If there is little or no test data, and the drained strength parameters are estimated based on typical values, assume c' = 0.

(5) Cohesion may be neglected to avoid progressive failures and/or instability due to softening. Because a fissured soil mass often has a lower strength than laboratory test samples, design values of c' (for peak strengths) should not exceed about 200 psf in overconsolidated clays that may be fissured.

(6) Fully softened strengths may be appropriate for highly plastic, clayey or silty soils in compacted embankments, or in excavations in overconsolidated soils. Fully softened strengths are applicable only for shallow depths along an embankment surface, perhaps to a maximum depth of about 10 feet (measured perpendicular to the ground surface).

(7) Where test data indicates a strength envelope with c' > 0, the value of ϕ' fit to the data may be used with an assumed value of c' = 0. Setting c' = 0 in this manner for an overconsolidated clay provides a conservative approximation of the fully softened strength envelope.

(8) If a value of c' > 0 is critical to the stability of the slope, drained shear tests and/or tests on fully softened samples should be considered to support the selection of an appropriate drained cohesion intercept.

7. Undrained Strength Parameters for Static, Short Term Conditions

7.1. Basis

Soil shear strengths are characterized using undrained strength parameters where or when pore water pressures are unknown or cannot be predicted with confidence. Typically representing conditions where shear induced pore water pressures (excess or deficient) have not dissipated, the undrained shear strength (S_U) of a soil is expressed using undrained strength parameters (c and ϕ):

$$S_u = c + \sigma'_{con} \tan\phi \qquad \textbf{Equation 25}$$

In practice, the undrained shear strength of a soil may be expressed using UU strengths (Section 7.3.1), "c/p" ratios (Section 7.3.2), or R-envelopes (Section 7.3.3). In each case, undrained strengths are characterized as a function of effective consolidation stress (σ'_{con}), or sometimes approximated as a constant within a soil zone.

Undrained strength parameters are used in "total stress" stability analyses, where excess pore water pressures generated by shearing are unknown. The effective stresses prior to loading (σ'_{con}) are used to quantify the soil strength, but the analysis is carried out using total stresses (pore pressures and effective stresses in the soil under load are not estimated). The underlying assumption is that excess pore pressures generated in a laboratory test specimen are similar to those encountered in the field, so that the fundamental effective stress is similar in both cases. Undrained strength parameters fit to test data implicitly represent the effects of excess pore water pressure on the soil strength in the field.

Some engineers refer to S_U, c, and ϕ as "total stress strength parameters." This causes confusion, because effective consolidation stresses are used with the parameters to compute the shearing resistance (FERC 2006). The term "undrained strength parameters" is thus recommended for S_U, c, and ϕ.

It is challenging to measure and quantify undrained shear strengths that accurately represent the behavior of soils in the field. The assessment of undrained shear strengths is discussed extensively by Ladd (1991), Terzaghi et al. (1996), Ladd and DeGroot (2003), and Duncan et al. (2014). Undrained strengths are dependent on a number of factors, including:

- structural anisotropy in the soil (bedding planes, fissuring, etc.),
- stress history (preconsolidation stress or overconsolidation ratio),
- water content, void ratio, and degree of saturation in the soil,
- sampling disturbance in test specimens,
- mode of shearing (stress path or stress induced anisotropy),
- strain rate dependency, including creep effects, and
- potential for progressive failure in sensitive soils.

7.2. When to Use Undrained Strengths

Shearing resistance is fundamentally related to the effective stress in a soil, and drained strength parameters should be used with effective stress analyses any time the pore pressures (including shear-induced pore pressures) can be reliably predicted. However, when the soil is loaded rapidly, or any time when the shear induced pore water pressures are difficult to accurately predict, effective stress analyses are impractical and undrained analyses are necessary.

Under static conditions, pore pressures equilibrate fairly quickly in high permeability soils, such that undrained shear strengths are usually associated only with clayey or silty soil deposits. Coarse grained soils (sands, gravels, etc.) are often permeable enough that excess pore pressures will rapidly dissipate, even under short term loading conditions. For pervious soils, whether saturated or unsaturated, drained effective stress strength parameters may be used to represent short-term, undrained conditions. This assumes the static or steady-state pore water pressures in the soil are unchanged by the short-term loading, and the shear strength in an "undrained analysis" can be modeled using the drained, effective stress strength parameters.

Earthquakes are an exception, however. Dynamic loading will usually cause excess pore pressures to accumulate even in coarse grained soils. Undrained strengths for seismic conditions (Section 9) are needed for most soils.

To determine if a particular soil will be "drained" under a static load, the Time Factor (T) can be computed:

$$T = \frac{c_v t}{D^2} \qquad \textbf{Equation 26}$$

where c_v is the coefficient of consolidation, t is the elapsed time for the loading condition, and D is the drainage distance. If the Time Factor is greater than or equal to about three ($T \geq 3$), the soil can be assumed to drain; otherwise the soil should be treated as undrained (Duncan et al. 2014). Judgment is usually required to estimate a representative drainage distance when computing the time factor. In most rapid drawdown analyses, full drainage can be assumed in soils having a hydraulic conductivity greater than 10^{-4} cm/sec (USACE 2003; Duncan et al. 2014). These guidelines are reasonable for judging if a soil zone should be modeled as drained or undrained in most slope stability analyses, except for seismic or impact load cases.

The flowchart in Figure 21 provides guidance in the selection of drained versus undrained strength parameters for different soil conditions, based on the assumptions for the analysis. Clean, coarse sands are usually assumed to be fully drained under most loading conditions, but should be treated as undrained under dynamic, seismic, or impact loads. Clean rockfill, including riprap, can generally be assumed to drain even in an earthquake. Drained or undrained strength parameters may be appropriate to represent the strength of unsaturated soils, as discussed in Section 8.

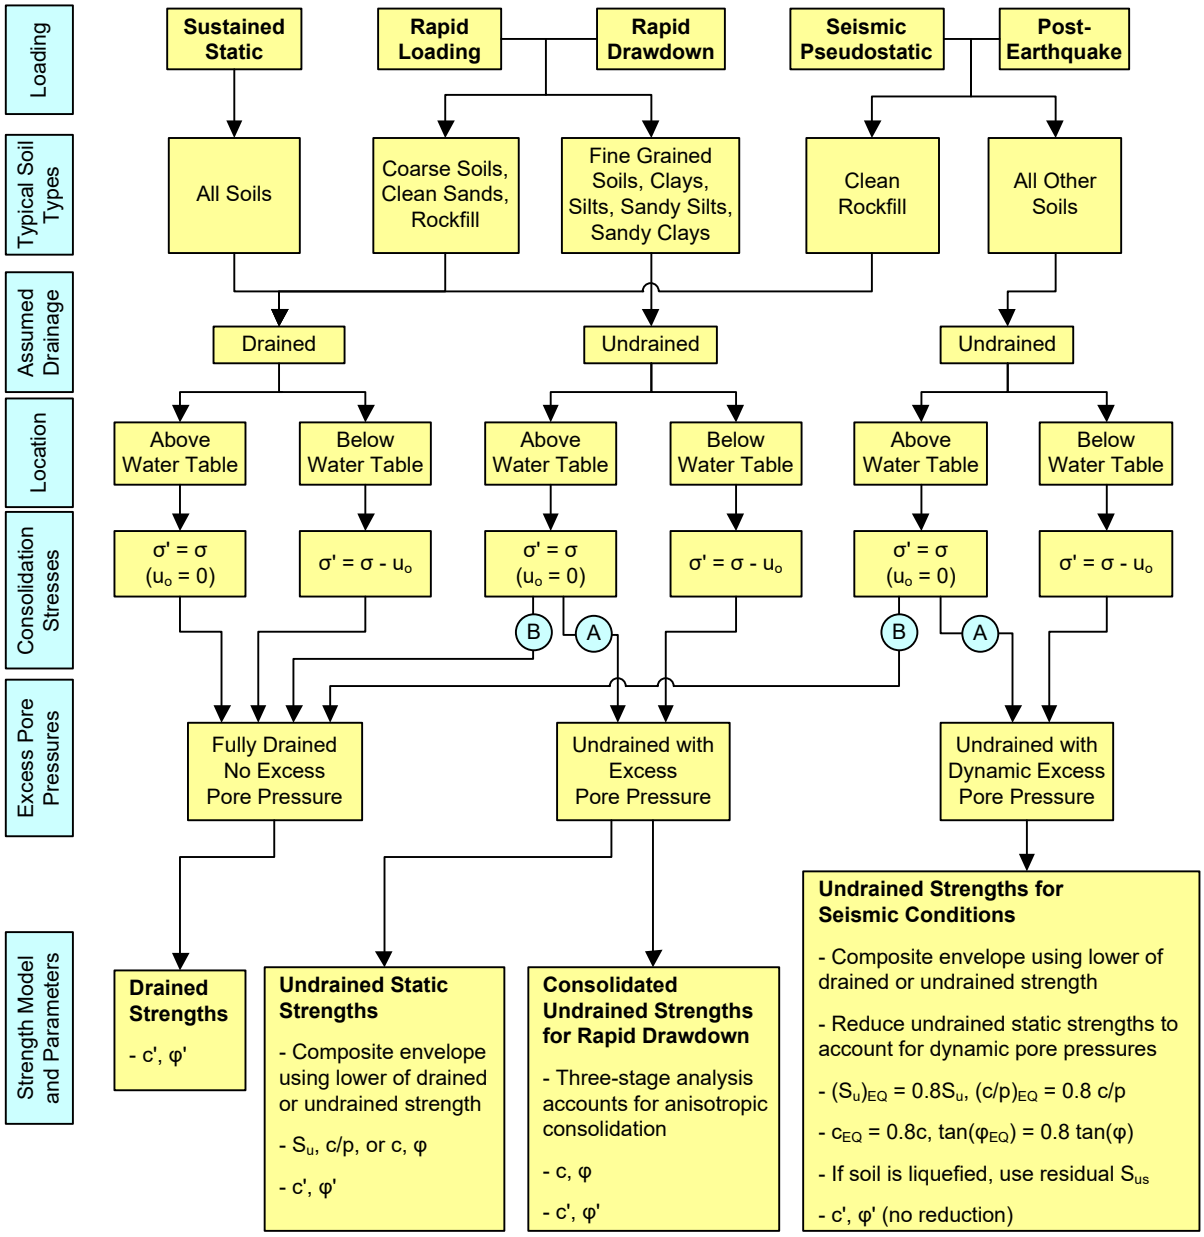

Figure 21. Selection of appropriate shear strength parameters for stability analyses.

7.3. Undrained Strength Parameters

7.3.1. UU Strengths

In unconsolidated undrained (UU) triaxial compression tests, soil samples are subjected to varying confining pressures and then loaded to failure. The samples are unconsolidated, in that no drainage from the soil is allowed as the confinement is increased. If the test samples are saturated, the applied confining pressure will cause a corresponding increase in pore pressure. Then, assuming all test samples are identical (same density), the effective stresses will be the same (in theory) regardless of the confining pressure. The undrained strength (S_U) is then independent of the confining stress ($\phi = 0$):

$$S_u = \text{constant} \qquad \textbf{Equation 27}$$

In practice, the void ratio of soil samples will decrease with depth and effective consolidation pressure, in samples taken from an otherwise uniform deposit. The undrained shear strength from UU tests will thus vary with the depth of the soil sample. In relatively thin or noncritical soil layers, a constant value of S_U may be used to model the entire deposit. In thicker deposits, values of S_U may be determined at various depths and the undrained strength profile might be modeled as a simple function of depth (z):

$$S_u = f(z) \qquad \textbf{Equation 28}$$

Unfortunately, the measurement of S_U in UU triaxial compression tests is fraught with problems, even when the tests are carefully executed in accordance with applicable standards. As detailed by Ladd (1991) and Ladd and DeGroot (2003):

- Unavoidable sample disturbance leads to S_U values that are too low.
- The high rate of shearing results in S_U values that are too high.
- Triaxial compression mode of shearing gives S_U values that are too high.

To get the "right" answer, these errors would have to offset one another. Engineering practice has generally assumed that the effects of sample disturbance dominate, leading to conservative measurements of S_U from UU tests. Ladd (1991) points out that this assumption may not be valid when better quality samples are obtained with modern tools and methods.

A value of S_U determined from a UU triaxial test is more appropriately viewed as an index of the soil's undrained strength, instead of a direct measurement. The relatively low cost of UU tests allows for conducting more laboratory runs, and can provide for a good compromise between testing costs and data quality. In addition, there is an extensive history of satisfactory performance when UU strengths are used in geotechnical design.

Historically, routine practice involved the use of unconfined compression tests to characterize the undrained shear strength (S_U = one half of the unconfined compressive strength) of clayey soils. However, unconfined compression testing

provides a poor, often low measure of soil strength. Specimens tend to dry during testing and, without confinement, dilatant soils are more apt to cavitate; both can cause desaturation of the soil. Unconfined tests should not be used with fissured clays, because of premature failure along the fissures (Terzaghi et al. 1996). UU triaxial tests, which involve little additional cost or effort, are nearly always preferred over unconfined compression tests.

7.3.2. c/p Ratios

To represent the variation in shear resistance with consolidation pressure, the undrained strength can be characterized using the "c/p ratio" ($c/p = S_u/ \sigma'_{1,con}$):

$$S_u = \left(\frac{c}{p}\right)\sigma'_{1,con} \qquad \textbf{Equation 29}$$

where $\sigma'_{1,con}$ is the major principal effective stress to which the soil has been consolidated. The c/p ratio concept is consistent with the experimental observation that the undrained strength of saturated clays varies with the water content (void ratio), which varies with the major principal effective stress to which the soil has been consolidated. The formulation in Equation 29, which avoids the theoretical limitations associated with R-envelopes (Section 7.4.3.3), is the preferred method for representing the undrained strength of soft, saturated soils.

The key to using this approach for a stability analysis is the determination of an appropriate, representative c/p ratio for the conditions of interest. Like S_U in general, values of the c/p ratio depend on the mode of shearing, stress history, sample disturbance, strain rate effects, etc. How these factors may be addressed in a laboratory testing program is outlined in Section 7.4.

For most normally consolidated soils, values of $c/p = 0.22 \pm 0.03$ are typical (Ladd and DeGroot 2003). The ratio will be larger for overconsolidated soils, and can be represented by the following empirical expression (Ladd 1991):

$$\left(\frac{c}{p}\right) = S \cdot OCR^{m} \qquad \textbf{Equation 30}$$

where S is an intercept value (where OCR = 1) and m is an empirical exponent (typical values of 0.75 to 1). Empirical values for estimating c/p ratios are presented in Section 7.6.

Here, the stress history of the soil deposit is represented by the OCR (overconsolidation ratio = preconsolidation pressure / effective stress). Application of Equation 30 in a stability analysis, and use of the c/p ratio in general, thus requires knowledge of the stress history. Accurate characterization of the preconsolidation stress (due to mechanical reductions in stress, desiccation, aging, or other physical-chemical process) is thus needed. Ladd and DeGroot (2003) provide specific recommendations for one dimensional consolidation testing to better quantify the preconsolidation stress.

The c/p approach works well for characterizing the undrained strength of soft clay deposits that are normally to moderately overconsolidated. In compacted embankments, where the preconsolidation stress is highly variable and difficult to quantify, the selection of a representative c/p ratio will be problematic. For unsaturated soils, the undrained strength measured in a UU test will vary with confining pressure, violating the assumption of $\phi = 0$. Therefore, c/p ratios are not recommended for modeling compacted embankment soils or unsaturated soils. Mohr-Coulomb strength parameters, or a single value of S_U (for layers or sublayers of moderate thickness), are usually better choices for such materials.

7.3.3. Undrained c and ϕ

The variation in undrained shear strength with consolidation pressure can also be represented using the Mohr-Coulomb envelope (Equation 19):

$$S_u = c + \sigma'_{con} \tan\phi \qquad \textbf{Equation 31}$$

where σ'_{con} is the effective consolidation pressure, and c and ϕ are undrained strength parameters (cohesion and friction angle, respectively).

This relationship gives the undrained strength on a potential slip surface as a function of the effective consolidation stress normal to the failure plane. When applied in a slope stability analysis, care must be taken to compute the undrained shearing resistance based on the normal stresses to which the soil has been consolidated (σ'_{con} in Equation 31). The steady state pore water pressures should be used in this calculation.

Traditionally, undrained strengths have been characterized using data from consolidated undrained (CU) laboratory tests that are fit with an "R-envelope" (traditional terminology employed by the U.S. Army Corps of Engineers). The undrained R-envelope (Figure 24) is a tangent line to "total stress" Mohr's circles, which are drawn for the consolidation pressure (σ'_{con}) and deviator stress at failure [$\sigma_{df} = (\sigma_1-\sigma_3)_f$]. When used to specifically represent R-envelopes, the undrained parameters are designated as c_R and ϕ_R.

The undrained shear strength obtained from a traditional R-envelope is less than the shear strength that would be measured in a CU test specimen at the same consolidation stress. This effect, and alternate definitions of the undrained strength envelope that may be employed, are discussed in Section 7.4.3.

7.4. Laboratory Measurements of Undrained Soil Strengths

7.4.1. Specimen Consolidation

Key details for handling soil samples and testing in the laboratory to measure undrained shear strengths in soft soils are provided in Ladd (1991) and Ladd and DeGroot (2003). High quality samples with minimal disturbance, generally obtained with thin-walled piston tube samplers, are essential for obtaining representative undrained strengths from laboratory tests. Even with careful handling of the field

sample and preparation of test specimens, the specimen will be affected by changes in stress during the extrusion process and the removal of the in situ stresses. Two methods may be employed during CU testing, to compensate for these effects:

- The Recompression technique (Bjerrum 1973) involves reconsolidating the test specimen back to the in situ stress conditions, prior to undrained shearing.

- The SHANSEP method (Ladd and Foott 1974) involves consolidating test specimens to stresses high enough to achieve virgin compression, then rebounding some so that the strength ratio can be characterized as a function of OCR (Equation 30).

The choice of methods depends on the nature of the soil being tested, as discussed by Ladd (1991), Ladd and DeGroot (2003), and Duncan et al. (2014). Where high quality block samples are available, the Recompression method is usually preferred. The SHANSEP method is preferred for normally to slightly overconsolidated clays, where Recompression to the in situ stress condition induces volumetric compression and a shearing resistance that is too high. The SHANSEP approach is often not practical for heavily overconsolidated soils, because of the high test pressures required; the Recompression technique should be used for such soils. Moreover, the Recompression technique should be chosen for highly structured, sensitive soils, where consolidation to virgin compression in the SHANSEP method will alter the soil structure and give undrained strengths that are too low.

Conventional laboratory triaxial tests consolidate test specimens under isotropic stress prior to undrained shear (designated as ICU or CIU tests). Testing anisotropically consolidated specimens (ACU tests) will generally produce higher and more accurate measurements of undrained shear strength. To simulate typical in situ stress conditions, Ladd (1991; Ladd and Foot 1974; Ladd and DeGroot 2003) advocates consolidating the test soils to K_o conditions ($\sigma'_h = K_o \sigma'_v$) in undrained tests designated as CK_oU.

Consolidated undrained test specimens are pressure-saturated prior to loading, to allow accurate measurement of pore water pressures. This eliminates suction pore pressures in unsaturated samples, but the absence of suction leads to conservative, lower shear strengths. Alternatively, the undrained shear strength of unsaturated soils can be characterized using UU triaxial tests.

7.4.2. Loading Path

The undrained strength also varies with the stress path imposed during shearing. The most commonly followed stress paths are triaxial compression (TC), triaxial extension (TE), and direct simple shear (DSS). Data presented in Terzaghi et al. (1996) and Ladd and DeGroot (2003) show that, for normally consolidated silts and clays:

$$\left(\frac{c}{p}\right)_{TC} > \left(\frac{c}{p}\right)_{DSS} > \left(\frac{c}{p}\right)_{TE} \qquad \textbf{Equation 32}$$

Duncan et al. (2014) point out that all three stress paths yield strengths that are lower than what would be measured under plane strain conditions. However, considering

the various modes of shearing in a slope stability problem, Ladd and Foott (1974) argue that DSS tests provide the best measure of the "average" shearing resistance along a potential slip surface.

Ladd (1991; Ladd and DeGroot 2003) favors the use of K_o-consolidated, direct simple shear (CK_oU-DSS) tests for providing the best measurement of undrained strength. Where DSS test data are not available, K_o-consolidated triaxial compression and triaxial extension tests (CK_oU-TC and CK_oU-TE) can be used. The average value of S_u from the TC and TE tests would then be used in the analyses. More importantly, Ladd argues that undrained strengths determined from CIU triaxial compression tests are too high and unsafe for design (see also Section 7.4.3).

7.4.3. Interpretation of Triaxial Test Data

When using data from laboratory triaxial tests, three different methods can be used to quantify the measured undrained shear strength. As described below, the undrained strength may represent the maximum shear stress $(S_u)_{ms}$, the shear stress from the R-envelope $(S_u)_R$, or the shear stress on the failure plane $(S_u)_{ff}$.

7.4.3.1. UU Tests - Maximum Shear Stress, $(S_u)_{ms}$

The shear strength measured in an unconsolidated undrained (UU) triaxial compression test represents the maximum shear stress in the soil at the time of failure. This shear strength, denoted $(S_u)_{ms}$, is the shear stress on a 45˚ plane in the triaxial test specimen. As depicted in Figure 22, $(S_u)_{ms}$ represents the top of the Mohr's circle of stress at failure, and is equal to one half of the applied deviator stress [$\sigma_{df} = (\sigma_1-\sigma_3)_f$]:

$$(S_u)_{ms} = \frac{\sigma_{df}}{2} \qquad \textbf{Equation 33}$$

The value of $(S_u)_{ms}$ is greater than the shear stress on the failure plane within the triaxial specimen. There are numerous other practical limitations associated with characterizing undrained strengths using UU test data, as outlined in Section 7.3.1. Strengths determined from UU triaxial compression tests represent an index of a soil's undrained shear strength. Hence, using $(S_u)_{ms}$ from a UU triaxial test is an acceptable means of characterizing the undrained shearing resistance on a potential failure surface in the field.

When using data from UU triaxial tests, the undrained shear strength in each test should be determined per Equation 33. Then, using the results from multiple tests, the undrained strength of the deposit may be characterized using:

- a constant value (Equation 27),
- a value that varies with depth (Equation 28), or
- a c/p ratio (Equation 29).

Depending on the quality and consistency of the samples, significant scatter or variation in the $(S_u)_{ms}$ values may be observed. A lower one-third value (where two-thirds of the values are higher), or perhaps the median value of $(S_u)_{ms}$, may be used to represent the soil. When using c/p ratios, a median or lower one-third value of the c/p ratio may be used.

7.4.3.2. CU Tests - Maximum Shear Stress, $(S_u)_{ms}$

To compensate for sample disturbance effects, undrained strengths can be measured using consolidated undrained (CU) triaxial tests. The undrained shear strength is sometimes taken as the maximum shear stress (Equation 33) in the test specimen at failure. The value of $(S_u)_{ms}$ is then plotted as a function of the effective consolidation stress (Figure 23). This interpretation is depicted on Figure 5.31 in Duncan et al. (2014).

However, values of $(S_u)_{ms}$ from CU triaxial compression results tend to be higher than the average shear strength that develops along a field failure surface, as discussed in Section 7.4.2. Therefore, the method shown in Figure 23 is <u>not</u> recommended for characterizing undrained strengths from CU test data.

7.4.3.3. CU Tests - Shear Stress from R-envelope, $(S_u)_R$

An R-envelope is developed by fitting a tangent line to Mohr's circles for the failure stresses measured in CU triaxial tests. The circles are drawn using the effective consolidation stress (σ'_{con}) as the minor principal stress and the deviator stress at failure (σ_{df}). The tangent R-envelope is then fit as shown in Figure 24, and characterized using Mohr-Coulomb parameters (c_R and ϕ_R).

$$(S_u)_R = c_R + \sigma'_{con} \tan \phi_R \qquad \textbf{Equation 34}$$

The strength parameters can also be determined by fitting a line to p-q points, as described in Section 5.2.

There are theoretical objections to the R-envelope formulation in Equation 34. The "Mohr's circles" are plotted using the effective stresses at the start of shearing and the stress difference at failure. Since these stresses do not exist at the same point in time, the plot is not actually a Mohr's circle (Duncan et al. 2014). Furthermore, Ladd (1991) argues that the R-envelope approach does not correctly represent the variation in undrained strength with the direction of the normal consolidation stress along a circular slip surface. The resulting errors are difficult to quantify.

On the other hand, R-envelopes have been widely used in past practice to represent the shear strength of soils under short-term conditions. This approach provides a conservative number for the undrained strength at a given consolidation pressure, as demonstrated in Section 7.4.3.5. For these reasons, a traditional R-envelope remains a valid approach for representing the variation in undrained shear strength with effective consolidation pressure. In particular, using the more conservative R-envelope may be preferred when characterizing the strength of a soil zone based on a limited number of CU test results.

R-envelope strength parameters (c_R, ϕ_R) are required for some analyses, such as for three-stage rapid drawdown calculations. That method explicitly accounts for the shear stress acting on the failure plane in a triaxial test sample.

7.4.3.4. CU Tests - Shear Stress on the Failure Plane, $(S_u)_{ff}$

In a triaxial compression test, failure should develop on a plane that is oriented at (45° + ϕ'/2) above horizontal (Duncan et al. 2014). The shear stresses on the failure plane can be determined using Mohr's circle. As depicted in Figure 25, a line drawn from σ'_{con} at (45° + ϕ'/2) above horizontal will intersect the Mohr's circle at the stresses on the failure plane. The shear stress on the failure plane at failure $(S_u)_{ff}$ can be computed using:

$$(S_u)_{ff} = \frac{\sigma_{df}}{2}\cos\phi' \qquad \textbf{Equation 35}$$

where σ_{df} is the measured deviator stress at failure. The shear stresses on the failure plane are employed explicitly in the three-stage calculation for rapid drawdown analyses.

The drained friction angle (ϕ') is required in Equation 35 to compute the shear stress on the failure plane in a CU test. Assuming pore pressures are measured, ϕ' can be obtained by fitting a drained strength envelope to data from the same CU test results. For a typical drained friction angle in the range of 30° to 35°, $(S_u)_{ff}$ will be 82% to 87% of the maximum shear stress $(S_u)_{ms}$.

Using data from several CU tests, the "undrained strength envelope" (FERC 2006; USBR 2011a) is fit to a plot of $(S_u)_{ff}$ versus specimen consolidation pressure (σ'_{con}). As illustrated in Figure 25, the undrained strength envelope is represented by Mohr-Coulomb parameters (c and ϕ).

Direct simple shear tests directly measure the consolidation pressure and shear stress on the (horizontal) failure plane. Hence, direct simple shear data can be fit directly to obtain c and ϕ.

Drained, undrained, and R strength envelopes are compared in Figure 26. Note that the values of c and ϕ for the undrained strength envelope are greater than c_R and ϕ_R for an R-envelope, which is tangent to the Mohr's circles of stress. Moreover, the undrained strength envelope should not be fit using p-q plots (Section 5.2).

7.4.3.5. Comparison of Shear Strengths from CU Tests

Three definitions for the undrained shear strength in a CU test are discussed above. For a certain consolidation pressure, these strengths will differ in magnitude as illustrated on Figure 27:

$$(S_u)_{ms} > (S_u)_{ff} > (S_u)_R \qquad \textbf{Equation 36}$$

Values of $(S_U)_{ms}$ from CU triaxial tests are unconservative and should not be used for design (Ladd 1991).

Values of $(S_U)_R$ may be obtained from R-envelopes fit to CU triaxial test results. This traditional approach tends to be conservative, in that the shear stresses within the triaxial sample are higher than the corresponding values of $(S_U)_R$ computed for the same consolidation pressure. This definition may be preferred when little test data is available to fit the strength envelope and a more conservative treatment is justified.

Values of $(S_U)_{ff}$ are rational and representative of the undrained strength measured in a CU triaxial test. The value $(S_U)_{ff}$ will always be higher than the corresponding value of $(S_U)_R$, and typically 80% to 90% of $(S_U)_{ms}$. This definition is justified when sufficient test data is available to perform a detailed or refined undrained analysis.

7.5. In Situ Measurements of Undrained Soil Strengths

Undrained shear strengths can also be assessed using in situ test methods, which avoid some of the problems related to sample disturbance in laboratory test specimens.

7.5.1. Standard Penetration Test Blowcounts

While values of S_U have been empirically related to Standard Penetration Test (SPT) data (Terzaghi et al. 1996), there is considerable uncertainty in such correlations. The rough correlation in Figure 28, from Peck et al. (1974), is qualitative in nature and should only be used to gauge the reasonableness of measured strengths. In very soft soils, SPT blowcounts (typically $N_{SPT} < 2$) are simply too insensitive for quantifying undrained strengths.

7.5.2. Cone Penetration Resistance

The tip resistance measured in a Cone Penetration Test (CPT) provides a better measurement of undrained shear strength in soft soils. The correlation is usually expressed as (Lunne et al. 1997):

$$S_u = \frac{q_t - \sigma_v}{N_{kt}} \qquad \textbf{Equation 37}$$

where q_t is the corrected CPT tip resistance, σ_v is the total overburden pressure, and N_{kt} is an empirical factor.

Unfortunately, the available empirical data show significant scatter, making the accurate quantification of S_U from CPT data difficult. Lunne et al. (1997) recommend

using N_{kt} = 15 to 20 as a preliminary estimate, while recognizing that values as low as N_{kt} = 10 may be appropriate for normally consolidated clays, and stiff fissured clays may exhibit N_{kt} = 30. To reduce this uncertainty, site-specific correlations between q_t and S_U (from field vane or laboratory testing) should be developed and used.

Ladd and DeGroot (2003) warn that poor quality CPT data, especially misleading pore pressure data, may undermine the reliability of such results. However, when used in conjunction with other site-specific measurements of undrained shear strength, CPT data can provide valuable knowledge on the variation of strength with location and elevation across the site.

7.5.3. Field Vane Shear Tests

The field vane (FV) shear test is generally considered the most reliable means of measuring undrained shear strength in situ. Recommended practice for FV testing includes the use of a thin vane blades with square ends, a gear system at the borehole surface (to rotate the vane at a controlled rate while accurately measuring the torque), and assessment of rod friction (Ladd and DeGroot 2003). To account for the effects of installation disturbance, fast rate of shearing, and the unique mode of failure, FV results should be adjusted using the Bjerrum's vane shear correction factor, μ (Figure 29). Values of μ were empirically determined using shear strengths back-calculated from slope failures.

Considering the scatter apparent in Figure 29, vane shear testing does not provide a precise measure of undrained shear strength. Despite this limitation, the vane shear test is the preferred test for measuring S_U in normally consolidated to moderately overconsolidated clays. The test results are less reliable where coarse inclusions (such as shells) are encountered (Ladd and DeGroot 2003). In silt deposits, which may be one to two orders of magnitude more permeable than clay, partial drainage is likely to occur in a vane shear test run at the standard rate of rotation. The measured shear resistance will then be higher than would be realized under fully undrained loading conditions.

7.6. Typical Values

Typical values and correlations are useful for making preliminary estimates of shear strengths, as well as for checking the reasonableness of field or laboratory test results. The table in Figure 28 indicates the range in S_U associated with the qualitative consistency of clays.

Mesri (1989) suggested this empirical relationship for S_U:

$$S_u = 0.22\,\sigma'_p \qquad \textbf{Equation 38}$$

where σ'_p is the preconsolidation pressure.

For soils with OCR = 1, the c/p ratio (Equation 29) has been empirically correlated to index properties as shown in Figure 30. Hansbo (1957) related the strength ratio in normally consolidated clays to liquid limit (LL):

$$\frac{c}{p} = 0.0045 \cdot LL \qquad \textbf{Equation 39}$$

Skempton (1957) related the strength ratio in normally consolidated clays to plasticity index (PI):

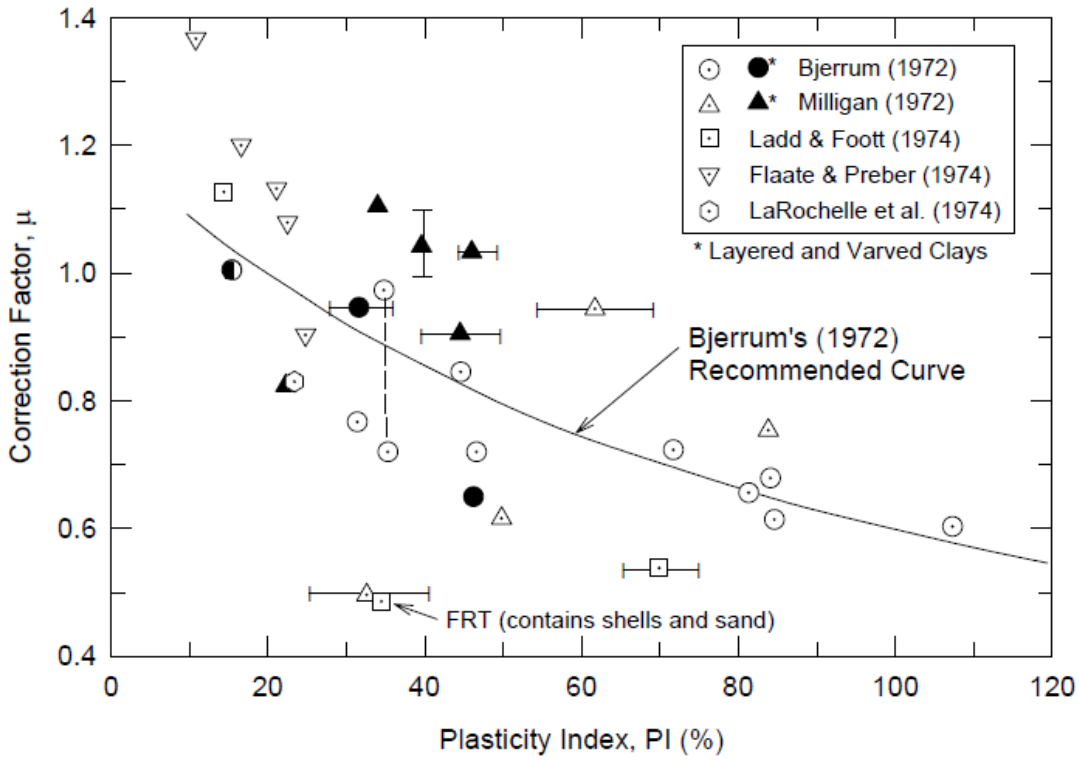
$$\frac{c}{p} = 0.11 + 0.0037 \cdot PI \qquad \textbf{Equation 40}$$

For normally consolidated to overconsolidated soils, typical values and correlations for S and m can be used with Equation 30 to estimate values of the c/p ratio. Suggested values of S and m for typical soils are listed in Figure 31.

Consistency	Field Identification	Undrained Shear Strength, S_u (psf)	Standard Penetration Test Blowcount* (blows/foot)
Very soft	Easily penetrated several inches by fist	< 250	< 2
Soft	Easily penetrated several inches by thumb	250 - 500	2 - 4
Medium	Can be penetrated several inches by thumb with moderate effort	500 - 1000	4 - 8
Stiff	Readily indented by thumb but penetrated only with great effort	1000 - 2000	8 - 15
Very stiff	Readily indented by thumbnail	2000 - 4000	15 - 30
Hard	Indented with difficulty by thumbnail	> 4000	> 30

** The correlation between undrained strength and SPT blowcount is rather unreliable*

Figure 28. Consistency of clays based on undrained strength (based on values from Peck et al. 1974).



$$S_u = \mu \left(S_u\right)_{vane}$$

Figure 29. Correction factor for the interpretation of undrained shear strengths from field vane shear tests (from Ladd and DeGroot 2003).

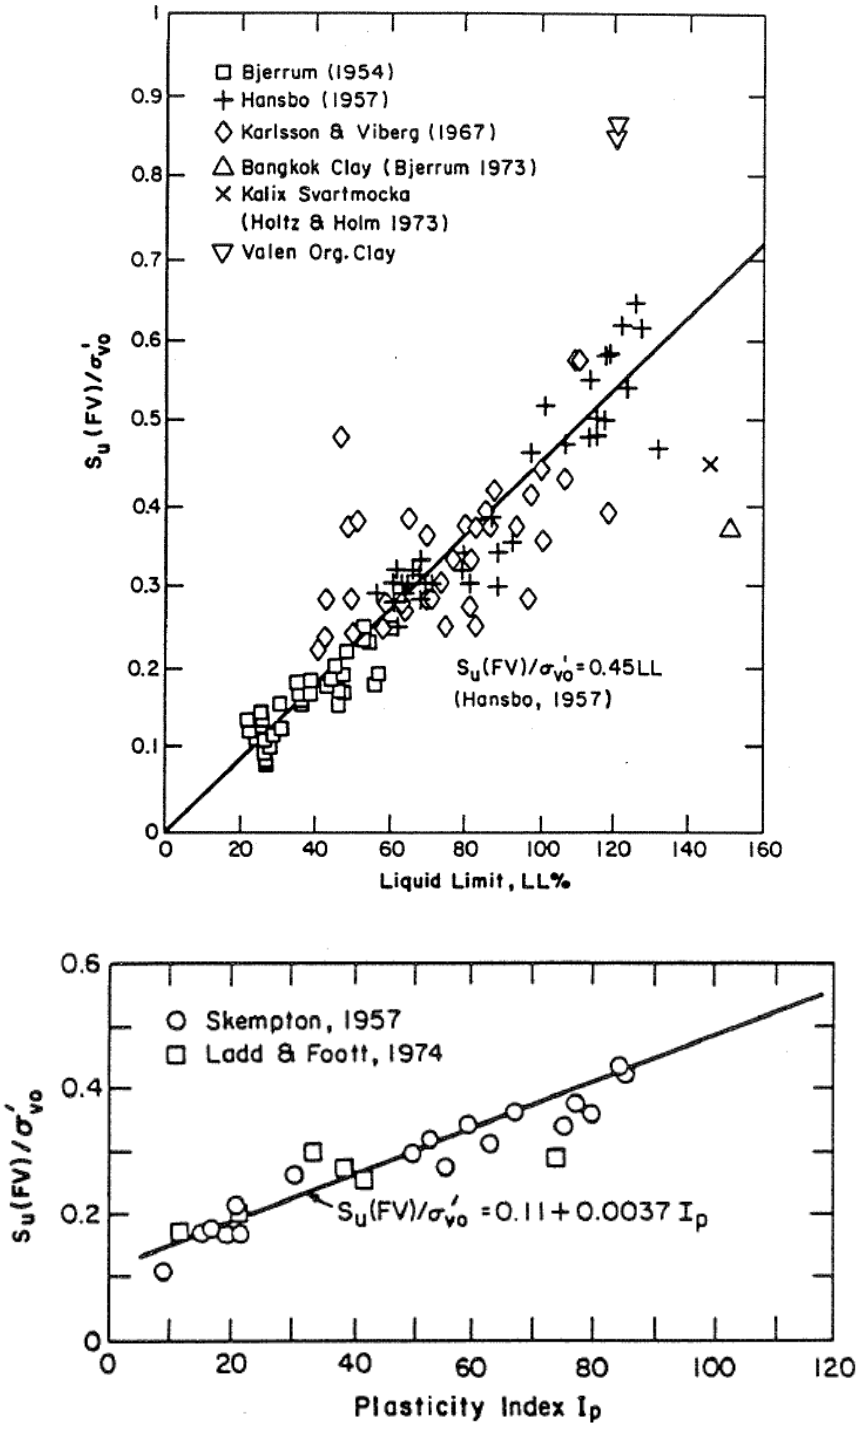


Figure 30. Correlations for c/p ratio in normally consolidated clays (from Duncan et al. 1989).

$$\left(\frac{c}{p}\right) = S \cdot OCR^{m}$$

Suggested, average values for most soils:

	S	m
Jamiolkowski et al. (1985)	0.23	0.8
Ladd (1991); Ladd and DeGroot (2003)	0.22 ± 0.03	0.8 ± 0.1

Suggested values for selected soils (Ladd and DeGroot 2003):

Soil Description	S	m[a]	Remarks
1. Sensitive cemented marine clays (PI < 30%, LI > 1.5)	0.20 Nominal SD = 0.015	1.00	Champlain clays of Canada
2. Homogeneous CL and CH sedimentary clays of low to moderate sensitivity (PI = 20 to 80%)	S = 0.20 + 0.05(PI/100) or Simply 0.22	$0.88(1 - C_s/C_c)$ ± 0.06 SD or simply 0.8	No shells or sand lenses-layers
3. Northeastern US varved clays	0.16	0.75	Assumes that DSS mode of failure predominates
4. Sedimentary deposits of silts and organic soils (Atterberg Limits plot below A-line) and clays with shells	0.25 Nominal SD = 0.05	$0.88(1 - C_s/C_c)$ ± 0.06 SD or simply 0.8	Excludes peat

[a] $m = 0.88(1 - C_s/C_c)$ based on analysis of CK_0UDSS data on 13 soils with max. OCR = 5 - 10

SD = standard deviation
C_s = swell index
C_c = compression index

Figure 31. Typical values for estimating the c/p ratio using Equation 30.

7.7. Recommended Practice

Accurately quantifying the shearing resistance of soils, when subjected to undrained loading, is a challenge. Where the stability of a slope depends on the behavior of soft or weak underlying soils, reasonable estimates of the undrained shear strength are

critical to the analysis and evaluation of the slope. This has been an active area for research throughout the history of modern geotechnical engineering, with disagreements and conflicting advice found in the literature. Moreover, there is usually a need to balance the need for accuracy and safety against the demands for engineering economy in the investigation, analysis, and design of earth structures. In these situations, the engineer must use appropriate judgment when specifying tests and selecting strength parameters for a stability analysis. It is neither feasible nor desirable to define a "recipe" procedure for selecting undrained soil strengths.

Based on the review outlined in this section, the following methods are recommended for the assessment of undrained soil strengths:

(1) Correlations and typical values for S_U and/or c/p ratios.

(2) Unconsolidated undrained (UU) triaxial compression tests:

- Perform numerous tests, measure S_U as one half of the deviator stress at failure, and expect significant scatter.
- Characterize S_U as a median value within a soil deposit, or as a function of depth.
- If there are sufficient data to characterize the consolidation pressure and stress history, characterize the variation in S_U using c/p ratios.

(3) Isotropically consolidated, undrained, triaxial compression tests (CIU TC):

- Fit a tangent line to Mohr's circles (or fit a line using p-q points), to define R-envelope parameters (c_R and ϕ_R). This is a traditional method that results in conservative values for the undrained shear strength, and is thus appropriate where few test results are available.
- Fit a line to the consolidation and shear stresses on the failure plane (Equation 35), to define parameters (c and ϕ) for the undrained strength envelope. This method is less conservative, and is recommended for refined analyses and where many test results are available.

(4) In situ field tests:

- Cone penetration tests (CPT) with site-specific correlations for S_U.
- Field vane (FV) shear tests, with empirical corrections (Figure 29) to obtain S_U.
- Characterize the results using a constant or representative S_U value, S_U expressed as a function of depth, or c/p ratios.

(5) Advanced laboratory testing:

- K_o-consolidated undrained triaxial compression (CK_oU TC) and triaxial extension (CK_oU TE) tests; use the average of S_U values measured in the two tests to define c/p ratios.

- K_o-consolidated direct simple shear (CK_oU DSS) tests, with results used to define c/p ratios.

Note that the use of c/p ratios requires knowledge of the stress history. In critical layers, one-dimensional consolidation tests are thus needed to define the variation in preconsolidation pressure with depth in the deposit. While c/p ratios work well for soft clay deposits, this approach is not recommended for characterizing unsaturated soils and/or compacted embankment soils.

In a roughly general sense, the costs and accuracy of the strength determination increases as one moves down the above list. Based on engineering judgment, more costly and better methods should be employed when characterizing more critical soil layers. Preliminary analyses accomplished with less expensive strength estimates may indicate the need for more in-depth considerations of stability, and the need for more sophisticated characterization of the undrained shear strength. More data from advanced testing can increase one's confidence in the strength parameters, which can also justify the use of smaller factors of safety and more economical designs.

7.8. Composite Drained-Undrained Strength Envelopes

Most soils will exhibit dilative shear behavior at low confining pressures. When saturated soils are consolidated to low effective stress and then sheared without drainage, the tendency to expand will cause decreasing pore pressures (suction). This results in increasing effective stress and shearing resistance, and an undrained strength that exceeds the drained strength. As indicated in Figure 32, the undrained strength envelope will be above the drained strength envelope in the regime of effective stress where the soil is dilative (generates suction pressures). Above a certain transition stress, the undrained strength will be less than the drained strength; in this higher stress range, the soil is contractive, creates increasing pressures in undrained shear, and the undrained strength is less than the drained strength.

The additional shearing resistance due to negative pore pressures may not be sustainable in the field. Over time, water will be drawn toward areas with suction pore pressures, the beneficial effects of the higher effective stress will be lost, and the soil strength will reduce to the drained shearing resistance. Hence, computed factors of safety for stability may be unconservative if some part of the slip surface has an undrained strength greater than the drained strength.

To avoid this issue, a composite (bi-linear) strength envelope (Figure 32) can be specified for undrained analyses. The undrained strength is then taken as the lesser of the undrained or drained strength envelopes at any given normal stress.

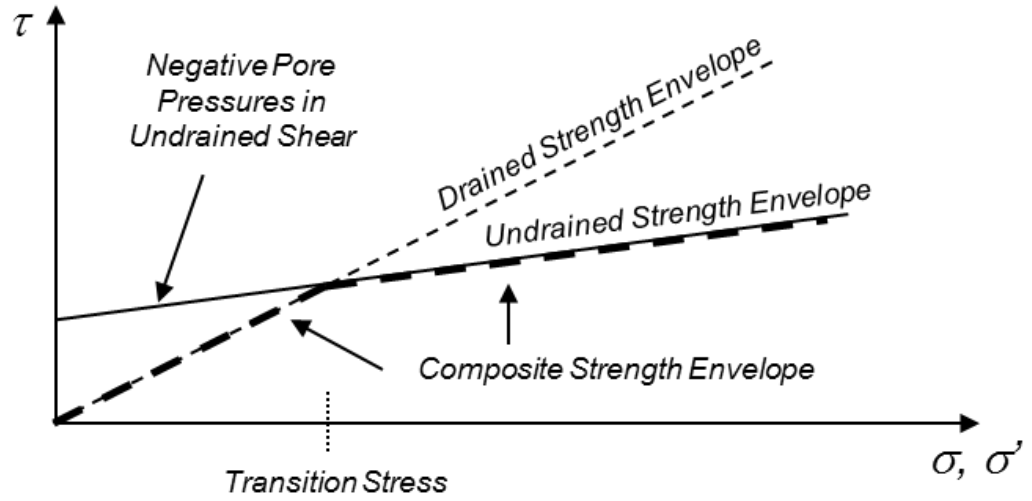

Figure 32. Specification of a composite strength envelope to avoid undrained shearing resistance due to negative pore pressures.

8. Strength of Unsaturated Soils

8.1. Saturation and Excess Pore Pressures

Shear-induced changes in pore pressure result from the movement of soil particles and the redistribution of stress between the soil skeleton and the pore fluid. Air is highly compressible, such that compression (or dilation) of pore space containing air does not generate significant changes in pore water pressure. In many unsaturated soils, shear induced volumetric changes will be accommodated by compression (or expansion) of the pore air. One might assume undrained loadings, including dynamic loadings, will not generate significant excess pore water pressures in these soils.

However, the actual behavior depends on the degree of saturation. Excess pore pressures are likely to occur in soils that are close to being saturated (perhaps at saturations greater than about 90 to 95%). For some soils above the water table, it will be appropriate and prudent to assume undrained loading will cause excess pore pressures and strength parameters should be assigned accordingly (Section 8.3).

Models of unsaturated soil behavior, including shear strength, can be formulated using the concept of "matric suction" (Fredlund and Rahardjo 1993). In most traditional geotechnical engineering problems, however, satisfactory results can be obtained without formal modeling of matric suction. Unsaturated soils may be modeled using conventional, drained or undrained strength parameters, as discussed below.

8.2. Conditions above the Water Table

The water table (phreatic surface) is defined as the line in the ground where pore water pressures are zero. Steady state pore pressures are positive beneath the water table and negative above.

Technically, the water table does not correspond to the top of the saturated zone. In the capillary fringe above the water table, the soils will be saturated or close to saturated. The height of capillary rise can range from a few inches in coarse sands to tens of feet in clayey soils.

In addition, soils above the water table may be saturated with retained water. For example, an embankment dam is subject to a changing phreatic surface as the reservoir rises and falls with dam operations. The phreatic surface drops when the pool is drawn down, inducing drainage from saturated zones above the new, lower water table. Significant water is retained in the pore spaces as the soil drains, with greater retention in finer grained soils. The infiltration and percolation of surface water will also increase the water content and degree of saturation in areas above the phreatic surface.

In assigning strength parameters for soils above the water table, it helps to consider how close to saturation the soil may be. Fine grained soils (silts, clays, sandy silts, sandy clays, etc.) are subject to greater heights of capillary rise, plus greater retention of draining or percolating ground water. Such soils may be close to saturation for

significant heights above the water table. Coarse sands with little fines experience less capillary rise and retain less water. The consideration of soil type is thus an important factor when selecting strength parameters for the unsaturated zone.

Regardless of saturation, the static pore pressures above the water table are negative (suction). Suction pressures increase the inter-particle stresses in the soil (represented by the effective stress) and the shearing resistance. However, in conventional stability calculations, pore pressures are assumed to be zero (absolute pressures equal to the atmospheric pressure) above the phreatic surface. Neglecting the suction pressures results in a conservative computation of consolidation stress and shearing resistance along the slip surface in the unsaturated zone.

8.3. Selection of Strength Parameters

The flowchart in Figure 21 helps to guide the selection of appropriate strength parameters for saturated and unsaturated soils. The chart is entered at the top, based on the loading condition that is being analyzed. Based on the loading rate and type of soil (see Section 7.2), each soil zone is judged to behave as fully drained or fully undrained. How the strengths are modeled may then depend on the whether the soil is found above or below the water table.

Under long-term, static loading conditions, the strength of all soils can be modeled using drained effective stress parameters. For clean, coarse soils, above or below the water table, drained strength parameters may be appropriate for all loads except dynamic, earthquake, or impact loads.

Rapid loading of fine grained soil induces undrained conditions in all cases, but the assigned strengths may differ if the soil is above or below the water table. Above the water table, the engineer has two options for the computing the strength under rapid or dynamic loads. The alternate paths are denoted A and B in Figure 21.

Along path A, excess pore pressures are assumed and undrained strengths are assigned (consolidation stresses are computed assuming zero static pore pressure). This path assumes the soil above the water table behaves as if it was saturated, and reduces the undrained strengths to account for dynamic pressures induced under seismic loading. This path leads to lower strengths and is thus conservative.

Path B in Figure 21 represents a less conservative approach that may be justified in some cases. For example, if the soil zone is well above the capillary fringe, the degree of saturation may be low enough to preclude the generation of excess pore pressures under load. This assumption may be valid for coarser soils that are closer to the water table. Along path B, drained strength parameters are assigned to zones above the water table.

For soils that are not located entirely above or below the phreatic surface, following path B will require specification of different soil zones above and below the water table (so that drained strengths can be assigned above, and undrained strengths can be applied below). The additional modeling effort may or may not be warranted or necessary, depending on the conditions under evaluation.

9. Undrained Strength Parameters for Seismic Conditions

9.1. Basis

Earthquakes generate cycles of shear stress that are rapid and transient. The stability of an earthen slope during an earthquake can be evaluated using pseudostatic analyses, simplified dynamic methods, or sophisticated numerical modeling. In each case, appropriate shear strength parameters must be estimated or measured for the undrained, seismic response of each soil.

To evaluate stability under these conditions, effective stress analyses (using c' and ϕ' strength parameters) are possible, but require a model for predicting the generation of excess pore water pressures under cyclic loading. A relatively high level of model sophistication is needed, along with good test data, to understand the volumetric response of the soil and track changes in effective stress during dynamic shearing.

A simpler approach is to use undrained stability analyses without predicting dynamic, excess pore pressures. Undrained shear strengths during an earthquake (S_{EQ}) can be characterized using undrained strength parameters, UU strengths, or c/p ratios:

$$S_{EQ} = c_{EQ} + \sigma'_{con} \tan\phi_{EQ} \qquad \textbf{Equation 41}$$

$$S_{EQ} = c_{EQ}, \text{ for } \phi_{EQ} = 0 \qquad \textbf{Equation 42}$$

$$S_{EQ} = \left(\frac{c}{p}\right)_{EQ} \sigma'_{1,con} \qquad \textbf{Equation 43}$$

Here, the "EQ" subscript designates parameters representing seismic (earthquake) loading conditions. Because cyclic shearing will generate additional pore pressures, above what might be expected under static shearing, undrained strengths for seismic loads (S_{EQ}) should be lower than for short-term static conditions (S_U). Much lower residual strengths (Section 10) are associated with soils that liquefy in an earthquake.

In most soils, the application of seismic shear stresses generates excess pore water pressures faster than they can dissipate. Undrained strength parameters are thus needed for most soils, even for granular soils that might be treated as fully drained under short-term, static loads. Exceptions might include clean gravels, rockfill, and stone riprap, all of which can usually be characterized using drained strength parameters in a seismic analysis.

9.2. Estimation of Dynamic Strengths

Cyclic shearing during an earthquake will generate additional pore water pressures in a soil. Higher pore pressures lead to softening and reduced shearing resistance, but soils that do not liquefy will retain most of their strength. Estimating appropriate strength parameters to represent these conditions is challenging. Given the inherent difficulties and incomplete knowledge of undrained soil behavior under dynamic loading,

geotechnical engineers have generally used judgment to arrive at appropriate strength parameters.

In their classic work on the seismic deformations of embankment dams, Makdisi and Seed (1977; 1978) recommended using a percentage of the static undrained shear strength to account for the potential loss of shearing resistance in unliquefiable soils during dynamic loading. They found that unliquefiable soils (clayey soils, unsaturated cohesionless soils, and very dense saturated cohesionless soils) exhibit essentially elastic behavior (no yielding) when subjected to many (> 100) cycles of stress at 80% or less of their static undrained shear strength. Substantial deformations generally result when these soils are loaded at higher cyclic shear stresses approaching their undrained shear strength. They thus concluded that for unliquefiable soils (i.e., soils that exhibit no more than small increases in pore pressure when loaded cyclically), the "cyclic yield strength" is, conservatively, at least 80% of the static undrained strength. Others have since used similar strength reductions to characterize the dynamic strength of unliquefied soils, in general.

Within the U.S. Army Corps of Engineers, Hynes-Griffin and Franklin (1984) recommend using reduced, undrained soil strengths in pseudostatic slope stability analyses. Specifically, they recommend using dynamic strengths equal to 80% of the undrained strength for both clays and unliquefied, pervious soils. While a reduced consolidated-undrained (R-type) strength envelope should be used for clayey soils, they recommend using a reduced, composite (bi-linear) drained-undrained (S-R type) envelope for pervious soils, to avoid relying on the increased shearing resistance due to decreasing pore pressures in dilative, granular soils (in this case, the drained strength parameters are not reduced).

Seed and Harder (1990) concluded that soils with a factor of safety against triggering of liquefaction (FS_{liq}) greater than 1.4 would experience only minor pore pressure generation under cyclic loading. Moreover, such soils could be represented in stability and deformation analyses using some large fraction of their static shear strength. For their analysis of the Lower San Fernando Dam failure, Seed and Harder (1990) assumed that granular soils with $FS_{liq} \geq 1.4$ retained 75% of their static strength (determined based on drained conditions) during the earthquake.

In summary, there is precedence for assuming that unliquefied soils will retain at least 80% of their static strength if they do not approach a liquefied state in an earthquake (U.S. Bureau of Reclamation 1999). This condition can be assumed to apply as long as $FS_{liq} \geq 1.4$ (the residual strength of liquefied soils is addressed in Section 10). A 20% reduction in strength can be represented using reduced short-term strength parameters:

$$c_{EQ} = 0.8\, c \qquad \textbf{Equation 44}$$

$$\tan(\phi_{EQ}) = 0.8 \tan(\phi) \qquad \textbf{Equation 45}$$

$$\left(\frac{c}{p}\right)_{EQ} = 0.8\left(\frac{c}{p}\right) \qquad \textbf{Equation 46}$$

When composite drained-undrained strength envelopes are used to avoid relying upon suction pressures for shearing resistance (Section 7.8), the drained strength parameters are not reduced.

9.3. Dynamic Strengths for Granular Soils

The residual strength of liquefied soils is discussed in Section 10.

As discussed in Section 7, undrained peak strengths are sensitive to a number of important details and can be difficult to accurately characterize. These difficulties are managed through the use of standardized test methods and prudent factors of safety, which have been established based on field experience. For fine-grained soils, there is a substantial base of experience, developed over the last century, to support the estimation, measurement, and appropriate application of undrained shear strengths to achieve acceptable field performance.

There is much less field or laboratory data, research, or design experience to support the selection of undrained strength parameters for unliquefied, clean, granular materials. Undrained loadings of such soils are uncommon, with the notable exception of seismic events. Laboratory determinations of in situ strengths are further inhibited by the great difficulty in obtaining undisturbed samples of these soils. Like clays, the determination of undrained yield strengths for sands from laboratory tests will be sensitive to details such as:

- relative density or void ratio of the test specimens,
- grain characteristics, including particle shape and gradation,
- effects of disturbance in "undisturbed" field samples,
- soil fabric resulting from the method of sample formation,
- consolidation stresses, including static shear stress,
- loading stress path (triaxial compression, extension, simple shear, etc.), and
- monotonic versus cyclic loading.

For sandy soils, the pre-earthquake shear strength under drained conditions (S_d, computed using effective stress) can be used to estimate the undrained shearing resistance (for undrained stability analyses) during and immediately after seismic loading. The 20% reduction in strength from the fully drained value is meant to account, in a simplistic manner, for the reduction in the undrained shearing resistance due to the generation of modest pore pressures during dynamic loading for unliquefied sands ($FS_{liq} \geq 1.4$). This approach has the advantage of indexing undrained strengths to ϕ', which can be estimated with relatively good confidence.

In addition, it is more difficult to reliably estimate peak undrained strength (S_U) than residual undrained strength (S_{us}) in a granular soil. Steady state concepts and back-analysis of liquefaction failures have been used to characterize residual strengths (Section 10.2), but ascertaining peak undrained strengths in field case histories is more difficult, and steady state concepts do not apply at the peak shear resistance. Hence, while considerable uncertainty remains in the estimation of residual strengths, peak undrained yield strengths can be estimated even less reliably. There is also a lack of field experience to judge what factors of safety should be considered adequate to ensure satisfactory performance, if that performance is predicted from such strength estimates.

9.4. Undrained Strengths for Pseudostatic Analyses

Pseudostatic stability calculations are carried out using limit equilibrium and the method of slices to compute a factor of safety for slope stability. The shearing resistance on the base of each slice can be computed using an undrained strength envelope (Equation 31), developed from consolidated undrained (CU) laboratory tests with a reduction for dynamic pore pressures (Section 9.2). The effective normal stresses on the base of each slice (σ'_{con} in Equation 31), representing the stresses to which the soil has been consolidated, should be computed using the steady state pore pressures prior to the earthquake.

In a simplified, single stage pseudostatic analysis, the value of σ'_{con} is computed from the total normal stress during the earthquake, which includes the inertial force (applied pseudostatic force). A more rigorous formulation involves a two-stage analysis (Duncan et al. 2014). The effective consolidation stresses normal to the failure surface (σ'_{fc}) are calculated in the first stage (without the pseudostatic force), and the undrained shear strength on that surface (τ_{ff}) is computed in the second stage calculations (with the pseudostatic force). A two-stage analysis requires a modified failure envelope:

$$\tau_{ff} = d_{EQ} + \sigma'_{fc} \tan\psi_{EQ} \qquad \textbf{Equation 47}$$

which can be derived from ϕ' and the seismic undrained strength parameters (c_{EQ} and ϕ_{EQ}):

$$d_{EQ} = c_{EQ}\left(\frac{\cos\phi_{EQ}\ \cos\phi'}{1-\sin\phi_{EQ}}\right) \qquad \textbf{Equation 48}$$

$$\psi_{EQ} = \arctan\left(\frac{\sin\phi_{EQ}\ \cos\phi'}{1-\sin\phi_{EQ}}\right) \qquad \textbf{Equation 49}$$

Duncan et al. (2014) considered a few typical cases, and concluded that a simplified, single-stage pseudostatic analysis should give a conservative estimate of the pseudostatic factor of safety in many cases.

10. Residual Strength Parameters for Liquefied Soils

10.1. Basis

A contractive, saturated sand sheared without drainage will exhibit a peak strength (S_u) followed by a residual shearing resistance with liquefaction at large strains. The residual strength (S_{us}), representing the shearing resistance of a liquefied soil in a steady state of deformation, may be very low. Some authors choose to identify the residual strength as S_r, to differentiate the residual, liquefied soil strength in the field from the steady-state strength in laboratory samples (Idriss and Boulanger 2008).

Soils are typically assumed to liquefy if the factor of safety against triggering of liquefaction (FS_{liq}) is less than or equal to 1.1. In their analysis of the Lower San Fernando Dam failure, for example, Seed and Harder (1990) assigned S_{us} values to soil zones that were indicated to have liquefied, based on $FS_{liq} \leq 1.1$.

The residual or steady state strength can be determined from laboratory tests on high quality "undisturbed" field specimens and reconstituted laboratory samples (Poulos et al. 1985). However, laboratory testing has been shown to give S_{us} values that are unconservatively high, compared to values back-calculated from field conditions (Castro et al. 1992; U. S. Bureau of Reclamation 1999). Correlations developed from liquefaction case histories and in situ penetration resistance (Section 10.2 and Section 10.3) are thus preferred for estimating S_{us} (USACE 2004).

10.2. Correlations based on SPT Blowcount

In the correlations presented in this subsection, the residual strength (S_{us}) or residual strength ratio (S_{us}/σ'_v) is related to SPT blowcount. Each of these correlations uses the corrected, normalized blowcount, $(N_1)_{60}$. The field blowcounts are normalized to one atmosphere of overburden pressure, corrected to 60% hammer efficiency, and adjusted for borehole diameter, short-rod energy loss, and sampler liner effects. The value of $(N_1)_{60}$ is the same as used to evaluate liquefaction triggering.

Some of the correlations presented below use SPT blowcounts that are also adjusted for the fines content of the soil. The corrected, clean-sand equivalent blowcount, $(N_1)_{60cs}$, is defined as:

$$(N_1)_{60cs} = (N_1)_{60} + \Delta(N_1)_{60cs} \qquad \textbf{Equation 50}$$

Approximate values of the fines content adjustment $\Delta(N_1)_{60cs}$ are:

% passing No. 200 sieve	$\Delta(N_1)_{60}$
10	1
25	2
50	4
75	5

Note that the above fines content correction, used in the residual strength correlations, is different than the fines content correction generally used in liquefaction triggering assessments.

Two published correlations for obtaining S_{us} from SPT blowcounts, both developed from limited case history data, are shown in Figure 33. Seed and Harder (1990) related S_{us} to the clean sand equivalent blowcount, while Stark and Mesri (1992) developed a correlation for the ratio of S_{us}/σ'_v. Seed et al. (2003) assert that Stark and Mesri's correlation is overly conservative at low pressure (σ'_v < 1 atm) and somewhat unconservative at high pressure (σ'_v > 3 atm). Seed et al. (2003) also acknowledge that the Seed and Harder (1990) correlation understates the influence of σ'_v on S_{us}.

According to Finn (1998), the practice at the U. S. Bureau of Reclamation has been to determine S_{us} at about the 35th percentile of Seed and Harder's (1990) correlation, using a line sketched between the upper and lower bounds. For $(N_1)_{60CS}$ greater than 15, Seed et al. (2003) recommend extrapolating the correlations in Figure 33 at constant slope. In addition, Seed et al. (2003) recommend that S_{us} should be limited to not exceed the fully drained shear strength (at the residual friction angle), which would require a reliance on significant negative pore pressures from the dilative response of soils at low pressures.

Olson and Stark (2002) used a larger case history dataset to develop correlations between the residual strength ratio and SPT blowcount (upper plot in Figure 34). The average trend line through the data is (Olson and Stark 2002):

$$\frac{S_{us}}{\sigma'_v} = 0.03 + 0.0075\,(N_1)_{60} \pm 0.03 \quad \text{for } (N_1)_{60} \le 12 \qquad \textbf{Equation 51}$$

where $(N_1)_{60}$ is the corrected, normalized SPT blowcount. The penetration resistance is not adjusted for fines content. A significant shortcoming of this correlation is the lack of field data for moderate to large confining pressures, corresponding to $(N_1)_{60}$ > 12.

Idriss and Boulanger (2008) examined the available case history data with the goal of providing better guidance on selecting strength ratios at higher penetration resistance. Among the challenges in developing these correlations, Idriss and Boulanger (2008) note the influence of "void redistribution" in a liquefied deposit, resulting from the migration of pore water within the soil during a liquefaction failure. Using the results from laboratory studies as a guide in extrapolating the case history data, Idriss and Boulanger proposed the two bounding relationships shown in the upper plot in Figure 35.

Where significant void redistribution might be expected, Idriss and Boulanger (2008) recommend a lower-bound estimate of residual strength ratio given by:

$$\frac{S_{us}}{\sigma'_v} = \exp\left[\frac{(N_1)_{60cs}}{16} + \left(\frac{(N_1)_{60cs} - 16}{21.2}\right)^3 - 3.0\right] \leq \tan\phi' \qquad \textbf{Equation 52}$$

Here, $(N_1)_{60CS}$ is the normalized, corrected SPT blowcount with the adjustment for fines content (Equation 50). The strength ratio is limited by the drained strength (tan ϕ'), based on the assumption that negative pore pressures (inferred by $S_{us} > \sigma'$ tanϕ') cannot be sustained. Significant void redistribution might be expected at "*. . . sites with relatively thick layers of liquefiable soil that are overlain by lower-permeability soils that would impede the post-earthquake dissipation of earthquake-induced excess pore water pressures*" (Idriss and Boulanger 2008). For example, Equation 52 would be appropriate for a thick layer of liquefied soil overlain by a clayey embankment.

Where void redistribution is judged to be unlikely, Idriss and Boulanger (2008) recommend an upper-bound estimate of residual strength ratio given by:

$$\frac{S_{us}}{\sigma'_v} = \exp\left[\frac{(N_1)_{60cs}}{16} + \left(\frac{(N_1)_{60cs} - 16}{21.2}\right)^3 - 3.0\right]\left[1 + \exp\left(\frac{(N_1)_{60cs}}{2.4} - 6.6\right)\right] \leq \tan\phi' \qquad \textbf{Equation 53}$$

This relationship is appropriately used for sites where void redistribution effects will be negligible. "*This condition could include sites where the stratigraphy would not impede post-earthquake dissipation of excess pore water pressures, [which] would be accompanied by densification of the soils at all depths*" (Idriss and Boulanger 2008). Where a rockfill dam is built over a relatively thin layer of liquefiable soil, for example, Equation 53 would be appropriate.

Various authors have preferred relationships between S_{us}/σ'_v and SPT blowcount. One can argue that penetration resistance should be correlated to S_{us}, instead of S_{us}/σ'_v. Steady state strengths measured in the laboratory have been shown to vary with void ratio (Poulos et al. 1985). After normalizing SPT blowcounts for the effects of overburden pressure, the value of $(N_1)_{60}$ should also correlate with the void ratio of a sandy soil. Hence, $(N_1)_{60}$ should correlate directly with S_{us}.

Three correlations for S_{us} in terms of $(N_1)_{60}$ or $(N_1)_{60cs}$ are shown in Figure 33a (Seed and Harder 1990), in the lower plot in Figure 35 (Idriss and Boulanger 2008), and in Figure 36 (Castro 1995). In Figure 36, the lower bound curve should be used to estimate liquefied strengths. Another correlation has been recently proposed by Kramer and Wang (2015):

$$\ln S_{us} = -8.444 + 0.109\,(N_1)_{60} + 5.379\,(\sigma'_v)^{0.1} \qquad \textbf{Equation 54}$$

where S_{us} and σ'_v are expressed in units of atmospheres.

10.3. Correlations based on CPT Tip Resistance

In addition to their correlation based on SPT blowcount, Olson and Stark (2002) used their database to develop a correlation between the residual strength ratio and CPT tip resistance (lower plot in Figure 34). The average trend line through the data is (Olson and Stark 2002):

$$\frac{S_{us}}{\sigma'_v} = 0.03 + 0.0143\,(q_{c1}) \pm 0.03 \quad \text{for } (q_{c1}) \le 6.5 \text{ MPa} \qquad \textbf{Equation 55}$$

Here, the normalized CPT tip resistance (MPa) is given by: $q_{c1} = 1.8 \cdot q_c / (0.8 + \sigma'_v/P_a)$. The penetration resistance is not adjusted for fines content. A significant shortcoming of this correlation is the lack of field data for moderate to large confining pressures, corresponding to $q_{c1} > 6.5$ MPa.

Idriss and Boulanger (2008) also used their database (Figure 35) to develop correlations based on CPT tip resistance. For sites without CPT data, they used empirical correlations to estimate the CPT resistance from the available SPT blowcounts. In these correlations, they use a CPT tip resistance (q_{c1N}) that is corrected for the effects of overburden pressure and normalized to a dimensionless value. The value of q_{c1N} is the same as used to evaluate liquefaction triggering.

Idriss and Boulanger (2008) also made an adjustment to account for the fines content of the soil. The normalized, clean-sand tip resistance, q_{c1Ncs}, is defined as:

$$q_{c1Ncs} = q_{c1N} + \Delta q_{c1N} \qquad \textbf{Equation 56}$$

Approximate values of the fines content adjustment Δq_{c1N} are:

% passing No. 200 sieve	Δq_{c1N}
10	10
25	25
50	45
75	55

Where significant void redistribution might be expected, Idriss and Boulanger (2008) recommend a lower-bound estimate of residual strength ratio given by:

$$\frac{S_{us}}{\sigma'_{vo}} = exp\left[\frac{q_{c1Ncs}}{24.5} - \left(\frac{q_{c1Ncs}}{61.7}\right)^2 + \left(\frac{q_{c1Ncs}}{106}\right)^3 - 4.42\right] \le tan\phi' \qquad \textbf{Equation 57}$$

Where void redistribution is judged to be unlikely, Idriss and Boulanger (2008) recommend an upper-bound estimate of residual strength ratio given by:

$$\frac{S_{us}}{\sigma'_{vo}} = exp\left[\frac{q_{c1Ncs}}{24.5} - \left(\frac{q_{c1Ncs}}{61.7}\right)^2 + \left(\frac{q_{c1Ncs}}{106}\right)^3 - 4.42\right]\left[1 + exp\left(\frac{q_{c1Ncs}}{11.1} - 9.82\right)\right] \le tan\phi' \qquad \textbf{Equation 58}$$

10.4. Recommended Practice

Considering the number of published correlations, and the uncertainty associated with each one, the recommended practice is to estimate S_{us} from all applicable correlations. The average or representative blowcount (or CPT tip resistance) in the soil layer should be used in the correlations to estimate S_{us}. Then, engineering judgment should be used to select an appropriate, representative value. Caution is needed to avoid over- or under-estimating S_{us} at confining pressures that are significantly higher or lower than the data set used to derive the correlations.

11. Residual Strength Parameters for Cyclic Softened Soils

For $FS_{\gamma=3\%}$ estimates less than one, the undrained strength may degrade during earthquake shaking. This behavior may be significant in deformation analyses. The post-earthquake strength of cyclic softened soils may range from the peak undrained strength (S_u) for small cyclic shear strains to the undrained, remolded strength (S_{ur}) at large cyclic shear strains. For clay-like soils with $FS_{\gamma=3\%}$ estimates less than one, using S_{ur} for softened soil horizons in an initial post-earthquake stability or deformation analysis can identify if the softened layers are a concern for post-earthquake stability. If this simple evaluation indicates a potential stability problem, additional evaluation is required to determine if S_{ur} or a greater strength is appropriate.

Laboratory strength tests for S_u and S_{ur} are typically required for high-consequence projects. Post-cyclic monotonic triaxial compression and direct simple shear tests are also valuable in identifying the degradation in peak undrained strength for modest strains. A more extensive discussion of laboratory test methods is provided in MSHA (2010).

11.1. Field and Laboratory Measurements of Remolded Strength

Measurement of S_{ur} requires a device that can achieve large strains, such as a field vane shear apparatus. Field tests are often performed adjacent to CPTs with pore pressure measurements to permit selection of suitable soil layers for testing. Field vane tests should follow accepted procedures, must be performed to high enough strains to mobilize S_{ur}, and must be conducted rapidly enough to capture the undrained behavior of the soil. Laboratory tests on saturated, remolded samples tested at the in situ water content may also be used.

Data from CPT can also be used to estimate remolded strength of clays. According to Lunne et. al (1997), the undrained, remolded shear strength (S_{ur}) of a clay is approximately equal to the sleeve friction measured with a CPT.

12. Properties of Rockfill

12.1. Basis

Coarse rockfill is difficult to characterize by testing. When a material contains cobbles or boulders, it is difficult to obtain representative samples and conduct meaningful tests with conventional laboratory equipment. Large-scale tests reported in the literature provide valuable data on the engineering properties of rockfill (Figure 39), but relatively few such tests have been published. However, appropriate properties can be usually selected on the basis of engineering judgment, where that judgment is supported by the performance of similar materials in other projects.

In the laboratory, the diameter of triaxial test specimens should be at least six times the size of the largest particle (Duncan et al. 2014). Most geotechnical laboratories have equipment for testing 4-inch diameter specimens, and a few facilities can test up to 12-inch samples. The largest particle size that can be tested in this equipment is then 0.7 to 2 inches. For gravelly soils, test samples re-mixed to have parallel grain-size distributions, or scalped to remove particles larger than one-sixth the specimen diameter, will generally have friction angles similar to the original material; however the relative density and gradation of the original material must be known with some confidence.

Testing samples without the largest particles is not recommended for rockfill with cobbles and boulders. There is a tendency for smaller particles to be stronger than larger particles (which may have internal fractures or discontinuities), and removing the larger particles may result in unconservative measurements of strength. Direct measurements on rockfill require testing large volumes of representative material. Few large triaxial compression apparatuses have been developed, and those were generally used for a specific project and are no longer in operation.

Fortunately, rockfill materials exhibit favorable engineering behavior. If the rockfill is relatively clean (voids between the larger rock particles are open), potential excess pore pressures will quickly dissipate. Depending on the gradation, fully drained conditions can often be assumed in rockfill under a variety of loading conditions, including under dynamic or seismic loads. Interlocking between large, angular pieces of durable rock will result in relatively high shear strength. Satisfactory performance in these materials can usually be demonstrated, even when conservative estimates of strength are used.

Published results from large-scale testing show how certain conditions affect the strength of rockfill. In general, friction angles decrease with increasing confining pressure, increasing particle size, and weathering over time. Well graded material generally has higher friction angles than poorly graded material. Angular to sub-angular material generally has higher friction angles than rounded to sub-rounded material. Mineralogy has little effect on friction angle.

Over a large pressure range, rockfill materials exhibit curved strength envelopes. This can be represented using secant friction angles that vary with confining pressure, as

discussed below. The secant friction angle (ϕ'_{sec}) is the slope of a tangent line to the Mohr's circle of stress at failure, with zero cohesion intercept, as depicted in Figure 37.

12.2. Historical Data

During construction of South Holston Dam, TVA performed large-scale tests to determine the friction angle of the quarried and dumped rockfill. Those tests, discussed by Leonard and Raine (1958), consisted of filling a 9.3-feet by 9.3-feet shear box with 6 to 12-inch diameter, quarried rock. The rockfill was vibrated during placement, and was about 3 feet thick when tested. Concrete slabs (total thickness of 6 feet) were placed on top of the apparatus for added confining load. Hydraulic jacks were used to apply a horizontal force until lateral displacement occurred. Three materials were tested: cemented sandstone, uncemented sandstone, and shale.

Data from the specific tests were not published, but Leonard and Raine (1958) reported measured friction angles of 45 degrees for the cemented sandstone, and about 30 degrees for the uncemented sandstone and shale. For design, a friction angle of 45 degrees was used for the downstream slope, where durable sandstone was placed. On the upstream face, a mix of the quarried rock was placed and a friction angle of 40 degrees was assumed. Although the method of measurement is unknown, Leonard and Raine (1958) report that dry unit weights for the rockfill were between 105 and 120 pounds per cubic foot.

The large-scale tests at South Holston Dam were conducted at rather low confining pressures (less than 900 psf). Granular materials, including rockfill, are known to exhibit curved failure envelopes, with secant friction angles that decrease at higher confining pressures. Hence, the South Holston friction angles reported by Leonard and Raine (1958) may be unconservatively high for representing the material strength under significantly higher confining pressures.

12.3. Published Research

Marachi et al. (1972) performed tests on 36-, 12-, and 2.8-inch diameter specimens of rockfill in drained triaxial compression equipment. Three types of rockfill were tested; argillite from Pyramid Dam, quarry blasted crushed basalt, and amphibolite from Oroville Dam. The test specimens were prepared to have grading curves parallel to the field gradation curves. The confining pressures for the tests ranged from 30 to 650 psi. The results of these tests (Figure 38) show a nonlinear Mohr-Coulomb strength envelope, with decreasing secant friction angles over the range of confining pressures tested. The results also show that for larger maximum particle size, the secant friction angle is less at a given confining pressure.

Leps (1970) compiled the database of rockfill test results in Figure 39, and showed the effects of normal pressure on drained friction angle. The data are plotted in Figure 40 on a semi-log graph of secant friction angle versus normal pressure. The data shows that at lower normal pressure, the decrease in friction angle is greater with increasing normal pressure than at higher pressures. The three trend lines in Figure 40 were defined by Leps (1970) for the range of typical rockfill; the trend lines can be represented by the following equations:

- Low density, poorly graded rockfill, with weak particles (unconfined compressive strength between 500 and 2,500 psi)

$$\phi'_{sec} = 41.8° - 6.8° \log\left(\frac{\sigma'_n}{P_a}\right) \quad \textbf{Equation 59}$$

- Average rockfill, with average strength particles (unconfined compressive strength between 2,500 and 10,000 psi)

$$\phi'_{sec} = 47.1° - 6.8° \log\left(\frac{\sigma'_n}{P_a}\right) \quad \textbf{Equation 60}$$

- High density, well graded rockfill with strong particles (unconfined compressive strength between 10,000 and 30,000 psi)

$$\phi'_{sec} = 52.1° - 6.8° \log\left(\frac{\sigma'_n}{P_a}\right) \quad \textbf{Equation 61}$$

Here, ϕ'_{sec} is the secant, effective stress friction angle (slope of a tangent line to the Mohr's circle of stress at failure, with zero cohesion intercept), σ'_n is the effective normal pressure on the failure plane, and P_a is one atmosphere of pressure in the units of σ'_n (P_a = 14.69 psi = 2,116 psf = 101.3 kPa).

Fell et al. (2005) present an empirical correlation, developed by Douglas (2003), for the secant friction angle of rockfill. This equation can be used to estimate the friction angle of the material using gradation data, normal stress, and unconfined compressive strength of the rock.

$$\phi'_{sec} = a + b\,{\sigma'_n}^{c} \quad \textbf{Equation 62}$$

$$a = 36.43 - 0.267ANG - 0.172FINES + 0.756(c_c - 2) + 0.0459(UCS - 150) \quad \textbf{Equation 63}$$

$$b = 69.51 + 10.27ANG + 0.549FINES - 5.105(c_c - 2) - 0.408(UCS - 150) - 0.408 \quad \textbf{Equation 64}$$

$$c = -0.3974 \quad \textbf{Equation 65}$$

ANG is a subjective rating for angularity; use ANG = 3 for crushed angular rock, ANG = 0 for rounded stone. FINES is the percentage of particles passing the No. 200 sieve (< 0.075 mm). From the gradation curve, c_c is the coefficient of curvature ($d_{30}^2/d_{10}d_{60}$). UCS is the unconfined compressive strength of the rock, in MPa, and σ'_n is the effective normal stress in kPa.

With this method, a multi-linear strength envelope can be used to represent the curved Mohr-Coulomb envelope typical of rockfill. This can be plotted by calculating ϕ'_{sec} at varying σ'_n applicable to the stability analysis. Loose dumped rockfill at low normal

pressures will have a secant friction angle approximately 4 degrees lower than calculated using this approach (Fell et al. 2005).

The method proposed by Douglas (2003) may be difficult to implement, because rockfill can be difficult to sample and the gradation may be unknown. If the rock is not durable, weathering may lead to significant changes in gradation over time after construction. The unconfined compressive strength may have to be estimated, if intact samples are not obtained. Finally, the subjective definition of "angularity" introduces additional uncertainty.

12.4. Curved Strength Envelopes in Slope/W

A single, representative friction angle can be selected to model the strength of a relatively thin or shallow rockfill layer. In deep rockfills, such as in the shell of a large rockfill dam, the confining pressure varies over a wide range and the strength model should represent a curved envelope, consistent with the test data discussed in Section 12.3. Some computer codes include an option for directly modeling variable secant friction angles, using equations like those in Equation 59 through Equation 61. The SLOPE/W code (from GEO-SLOPE International, Ltd) does not include this option, but will allow the user to specify points on a curved strength envelope. This can be accomplished using the procedure outlined below.

A curved strength envelope and a secant friction angle (for the Mohr's failure circle at one confining stress) are depicted schematically in Figure 37. Technically, the line at ϕ'_{sec} is not tangent to the Mohr's circle of stress at the same point as for the curved strength envelope, but the difference is not significant. Points on the curved strength envelope can be computed as follows:

(1) Select a range of normal stresses (σ'_n) that span and bracket the problem of interest.

(2) At each σ'_n, determine an appropriate ϕ'_{sec} for the material (for example, using the empirical equations in Section 12.3).

(3) At each σ'_n, compute the shear stress on the failure surface (τ_f) using:

$$\tau_f = \sigma'_n \tan \phi'_{sec} \qquad \textbf{Equation 66}$$

(4) Include a point at the origin ($\sigma'_n = 0$, $\tau_f = 0$), even if ϕ'_{sec} is not defined at zero stress.

These values of (σ'_n, τ_f) are then entered into SLOPE/W, which will interpolate between the entered values (using a spline function) to obtain the shear resistance at any normal effective stress.

SLOPE/W requires linear strength envelopes for three-stage rapid drawdown analyses. In this case, the needed strength parameters can be obtained from an approximate, straight line fit to values of (σ'_n, τ_f) in the appropriate stress range.

APPENDIX F – COMMON PROCEDURES IN SEISMIC ANALYSIS OF SOIL AND ROCK

Common Procedures in Seismic Analysis of Soil and Rock

Purpose:

- This appendix presents common procedures for the seismic analysis of soil and rock, such as Ground Response Analysis, Liquefaction Analysis, Cyclic Softening of Clay-Like Soils, and Seismic Deformation Analyses.

Developed by: Stantec Consulting Services Inc.	
Prepared by: Kirk Jenkins	*Reviewed by:* Jeff Dingrando
Date: 4/16/2020	

Table of Contents

TABLE OF CONTENTS **2**

LIST OF FIGURES **3**

1. INTRODUCTION **4**

2. GROUND RESPONSE ANALYSIS **5**
2.1. HARD ROCK SEISMIC MOTIONS 6
2.2. MODULUS REDUCTION AND DAMPING CURVES FOR SOIL 7
2.3. MODULUS REDUCTION AND DAMPING FOR ROCK 12
2.4. PROFILES ANALYZED 13
2.5. GROUND RESPONSE OUTPUTS 14

3. LIQUEFACTION ANALYSIS **16**
3.1. INITIAL SCREENING FOR SOIL BEHAVIOR 16
3.1.1. Effect of Soil Fines on Liquefaction Susceptibility 16
3.1.2. Sand-Like versus Clay-Like Soils 16
3.2. LIQUEFACTION OF SAND-LIKE SOILS 18
3.2.1. Factor of Safety for Liquefaction 19
3.2.2. Cyclic Stress Ratio 19
3.2.3. Cyclic Resistance Ratio for Sand-Like Soils 20
3.2.4. Corrected Standard Penetration Test Blowcounts 24
3.2.4.1. SPT Blowcount Correction for Drilling and Sampling Techniques 24
3.2.4.2. SPT Blowcount Correction for Overburden Stress 27
3.2.5. Clean-Sand Equivalent SPT Blowcounts 28
3.2.6. Corrected Cone Penetration Tip Resistance 30
3.2.7. Clean-Sand Equivalent CPT Tip Resistance 33
3.2.8. Magnitude Scaling Factor for Sand-Like Soils 35
3.2.9. CRR Correction for Overburden Stress in Sand-Like Soils 36
3.2.10. CRR Correction for Static Shear Stress in Sand-Like Soils 39
3.2.11. Liquefaction Resistance based on Shear Wave Velocity 42
3.3. CYCLIC SOFTENING OF CLAY-LIKE SOILS 42
3.3.1. Screening for Susceptibility to Cyclic Softening 42
3.3.2. Factor of Safety for Cyclic Softening 44
3.3.3. Cyclic Resistance Ratio for Clay-Like Soils 45
3.3.4. Magnitude Scaling Factor for Clay-Like Soils 45
3.3.5. CRR Correction for Static Shear Stress in Clay-Like Soils 45

1. INTRODUCTION

This appendix presents common procedures for the seismic analysis of soil and rock, such as Ground Response Analysis, Liquefaction Analysis, Cyclic Softening of Clay-Like Soils, and Seismic Deformation Analyses.

2. GROUND RESPONSE ANALYSIS

One-dimensional, equivalent linear ground response analyses were performed to predict ground motions (acceleration time histories) at points within the unit and foundation during a seismic event. As depicted schematically in Figure 1, the analysis involves the numerical propagation of an earthquake ground motion time history, input at the top of hard rock, upward through the one-dimensional, vertical profile of firm rock, soft rock, foundation soil, and embankment materials at a particular location. The nonlinear behavior of soil is represented with strain compatible elastic properties.

The following assumptions are made in one-dimensional ground response analyses:

- The soil and rock system extends infinitely in all horizontal directions.
- Each soil and rock deposit in the system is completely defined by its thickness, unit weight, secant shear modulus, and damping ratio.
- The strain dependence of modulus and damping is accounted for by an equivalent linear procedure, based on an average effective strain level computed for each layer.
- The responses in the system are caused by the upward propagation of shear waves from the underlying hard rock formation.
- The shear waves are given as acceleration values at equally spaced time intervals; cyclic repetition of the acceleration time history is implied in the solution.

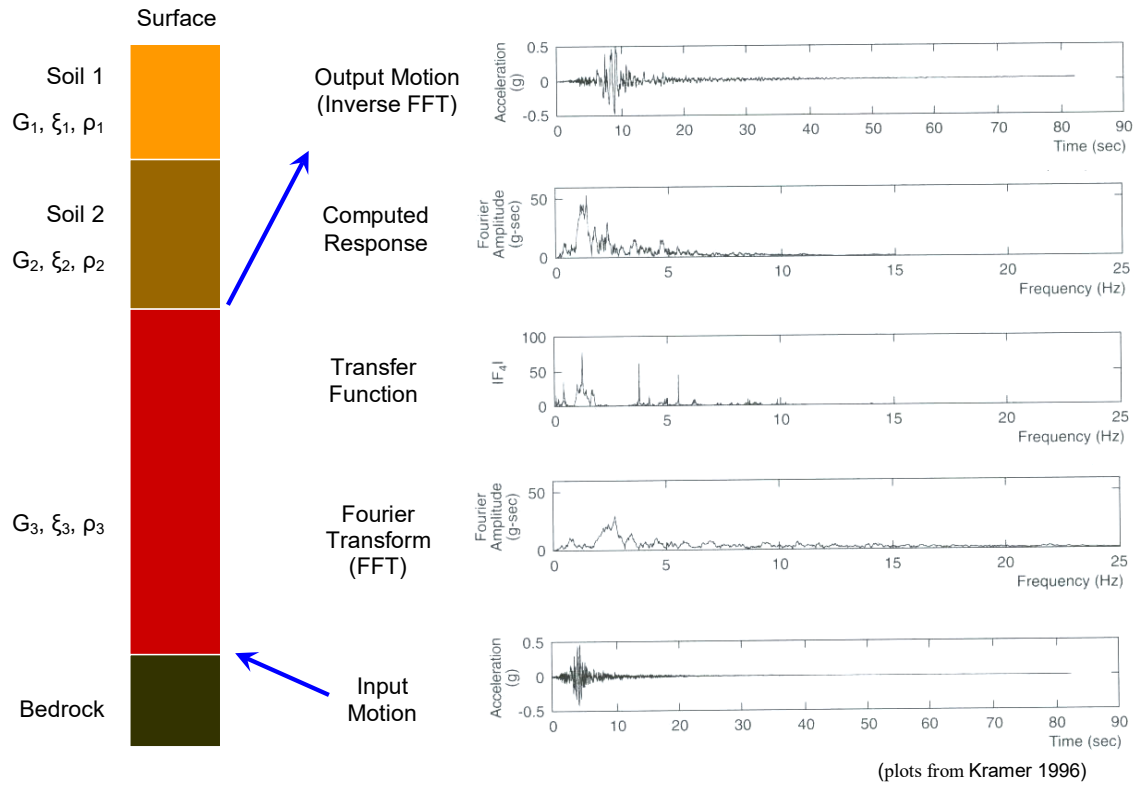

Figure 1. Conceptual Sketch of 1D Ground Response Analyses

2.1. HARD ROCK SEISMIC MOTIONS

The ground response analyses model the upward propagation of shear waves, from the time history of seismic accelerations in hard basement rock up to the ground surface. Multiple acceleration time histories, representing the expected ground motions for each of the scenario earthquakes, were obtained for this specific site.

In attenuation models, seismologists (including those employed by TVA for this study) commonly define “hard rock” as material with a shear-wave velocity of 9,200 ft/sec or greater, at the surface or very shallow depths. In the Central and Eastern North America (CENA), seismologists often treat the Pre-Cambrian basement rock as "hard rock"; all rock above that is assumed to be "firm rock", which is modeled in the site response analysis. At TVA’s plant sites, the top of hard basement rock is thousands of feet below the surface. Depending on the site geology, certain layers above the basement may have shear wave velocities greater than 9,200 ft/sec, but these layers are not the basement hard rock.

Unfortunately, there is significant uncertainty associated with the shear wave velocities, modulus reduction, and damping properties over the great thickness of firm rock units, above the very deep hard

basement rock. Assumptions for these firm rock properties, particularly the damping, can strongly influence the results from the ground response analyses (high frequency motions may be significantly attenuated by damping over the substantial thickness of firm rock). To reduce the impact of this uncertainty, the input motions were applied at a shallower point in the firm rock column. Specifically, per TVA (2016) the input acceleration time histories were applied in the bedrock profile where there are continuous layer(s) of underlying rock, at least 1,000 feet thick, with an average shear wave velocity of 8,000 ft/sec or greater.

Multiple time histories are considered for a specific design earthquake, to account for the significant uncertainty in predicting acceleration time histories in a future seismic event. For each of these ground motions, three orthogonal components are provided (two horizontal and one vertical). While all three components are considered for concrete structures, only the two horizontal components are evaluated for earth embankment structures.

The vertical loading is typically neglected in the dynamic analysis of embankments, because:

- horizontal motions are usually of greater amplitude than the vertical motions (except in close proximity to the seismic source);
- vertical ground motions induce significantly smaller shearing strains than horizontal motions; and
- transient isotropic-compression strains associated with vertical ground motions do not generate significant excess pore pressures and soil strength degradation.

In current engineering practice, multiple ground motions are also used to evaluate the seismic response of buildings. Per ASCE (2010), structural performance is judged based on the mean prediction if seven or more ground motion pairs or sets are analyzed. If less than seven ground motion sets are evaluated, the maximum prediction is used to judge performance of a structure for a particular design earthquake. This framework is adopted here for the evaluation of earth structures. For a given scenario earthquake:

- If seven or more ground motion sets are evaluated, the mean predicted seismic response may be used to assess performance.
- If less than seven ground motion sets are evaluated, the maximum predicted seismic response should be used to assess performance.

These criteria apply for the calculation of maximum or mean displacement, cyclic stress, or other measure of seismic response for the earth structure.

2.2. MODULUS REDUCTION AND DAMPING CURVES FOR SOIL

Soils begin to soften at shear strains exceeding some small threshold level. The softening dynamic response can be represented with shear modulus reduction and damping ratio curves, expressed as functions of the cyclic shear strain (Kramer 1996). Normalized shear moduli (G/G_{max}) are used, where G is the secant shear modulus and G_{max} is the shear modulus at very small strains (G_{max} is related to mass density and shear wave velocity).

To represent the cyclic response of soil in a ground response analysis, the following material parameters are thus required:

- Small-strain shear modulus (or shear wave velocity and mass density).
- Relationship between normalized shear modulus and cyclic shear strain.
- Relationship between the critical damping ratio and cyclic shear strain.

A number of modulus reduction and damping curves have been published for various material types. In this analysis, the empirical equations developed by Darendeli and Stokoe (2001) were used to estimate the modulus and damping curves for each soil. These empirical relationships, detailed in Equation 1 through Equation 12, are written as functions of plasticity index (PI) and mean effective stress (σ'_m). Overconsolidation ratio, frequency, and number of cycles are all assumed to be 1, 1 Hz, and 10 cycles, respectively, as recommended by Darendeli and Stokoe (2001). The modeled dynamic stiffness thus varies with stress level, as needed when analyzing deep soil profiles (greater than about 100 feet).

Modulus reduction curves are calculated as follows:

$$\frac{G}{G_{max}} = \frac{1}{1 + \left(\frac{\gamma}{\gamma_r}\right)^a} \quad \textbf{Equation 1}$$

where γ is shearing strain, γ_r is reference strain, and a is a curvature coefficient. γ_r and a are calculated as follows:

$$\gamma_r = \left(\phi_1 + \phi_2 * PI * OCR^{\phi_3}\right) * {\sigma'_o}^{\phi_4} \quad \textbf{Equation 2}$$

$$a = \phi_5 \quad \textbf{Equation 3}$$

$$\phi_1 = 0.0352 \quad \textbf{Equation 4}$$

$$\phi_2 = 0.0010$$

$$\phi_3 = 0.3246$$

$$\phi_4 = 0.3483$$

$$\phi_5 = 0.9190$$

where σ'_o is mean effective confining stress in atmospheres, PI is soil plasticity index in percent, OCR is overconsolidation ratio (assumed to be 1), and ϕ_1 through ϕ_5 are parameters that relate the normalized modulus reduction curves to soil type and loading conditions.

Damping curves are calculated as follows:

$$D = F * D_{Masing} + D_{min} \quad \textbf{Equation 5}$$

$$D_{Masing} = c_1 D_{Masing,a=1.0} + c_2 {D_{Masing,a=1.0}}^2 + c_3 {D_{Masing,a=1.0}}^3 \quad \textbf{Equation 6}$$

$$D_{Masing,a=1.0} = \frac{1}{\pi}\left[4\frac{\gamma - \gamma_r \ln\left(\frac{\gamma+\gamma_r}{\gamma_r}\right)}{\frac{\gamma^2}{\gamma+\gamma_r}} - 2\right] \quad \textbf{Equation 7}$$

$$c_1 = -1.1143a^2 + 1.8618a + 0.2523 \quad \textbf{Equation 8}$$

$$c_2 = 0.0805a^2 - 0.0710a - 0.0095$$

$$c_3 = -0.0005a^2 + 0.0002a + 0.0003$$

$$F = b * \left(\frac{G}{G_{max}}\right)^{0.1} \quad \textbf{Equation 9}$$

where *b* is a scaling coefficient, D_{Masing} is damping estimated based on Masing Behavior, and D_{min} is small strain material damping ratio. *b* and D_{min} are defined as follows:

$$D_{min} = \left(\phi_6 + \phi_7 * PI * OCR^{\phi_8}\right) * \sigma_o'^{\phi_9} * [1 + \phi_{10} * \ln(frq)] \quad \textbf{Equation 10}$$

$$b = \phi_{11} + \phi_{12} * \ln(N) \quad \textbf{Equation 11}$$

$$\phi_6 = 0.8005 \quad \textbf{Equation 12}$$

$$\phi_7 = 0.0129$$

$$\phi_8 = -0.1069$$

$$\phi_9 = -0.2889$$

$$\phi_{10} = 0.2919$$

$$\phi_{11} = 0.6329$$

$$\phi_{12} = -0.0057$$

where *frq* is loading frequency (assumed to be 1 Hz), *N* is number of loading cycles (assumed to be 10), and ϕ_6 through ϕ_{12} are parameters that relate material damping curve to soil type and loading conditions.

To implement Darendeli and Stokoe's (2001) modulus reduction and damping curves in Strata (Kottke et al. 2013), several modulus reduction and damping curves, each one characterizing a range of plasticity index (PI) and mean effective stress (σ'_m) values, were added to the software's curve library. Ten "bins" of PI and σ'_m (in pounds per square foot, psf) were defined, for these ranges in value:

Range in Plasticity Index	Range in Mean Effective Stress (psf)
0	0 - 400
0 - 10	400 - 800
10 - 15	800 - 1,600
15 - 20	1,600 - 2,500
20 - 25	2,500 - 5,000
25 - 30	5,000 - 7,500
30 - 40	7,500 - 10,000
40 - 55	10,000 - 17,000
55 - 70	17,000 - 25,000
70 - 100	25,000 - 42,000

In total, 100 curves were generated (ten PI bins, each associated with ten σ'_m bins). Average values, at the midpoint of the bin ranges, were used in the calculation of each curve. For example, PI = 5 and σ'_m = 200 psf were used to calculate the modulus reduction and damping curves representing a soil with a PI between 0 and 10, at a mean stress between 0 psf and 400 psf. Bin ranges were selected such that the intervals between modulus reduction and damping curves would be well distributed over the full range of PI and σ'_m.

Ishibashi and Zhang (1993) modulus reduction curves can yield a G/G_{max} value greater than 1.0. The curves implemented in Strata truncate the G/G_{max} curves at a maximum value of 1.0. This constrained value of G/G_{max} was then used when developing the damping ratio curves implemented in Strata. The effective mean pressure is computed assuming the at-rest earth pressure coefficient (K_o) is 0.5.

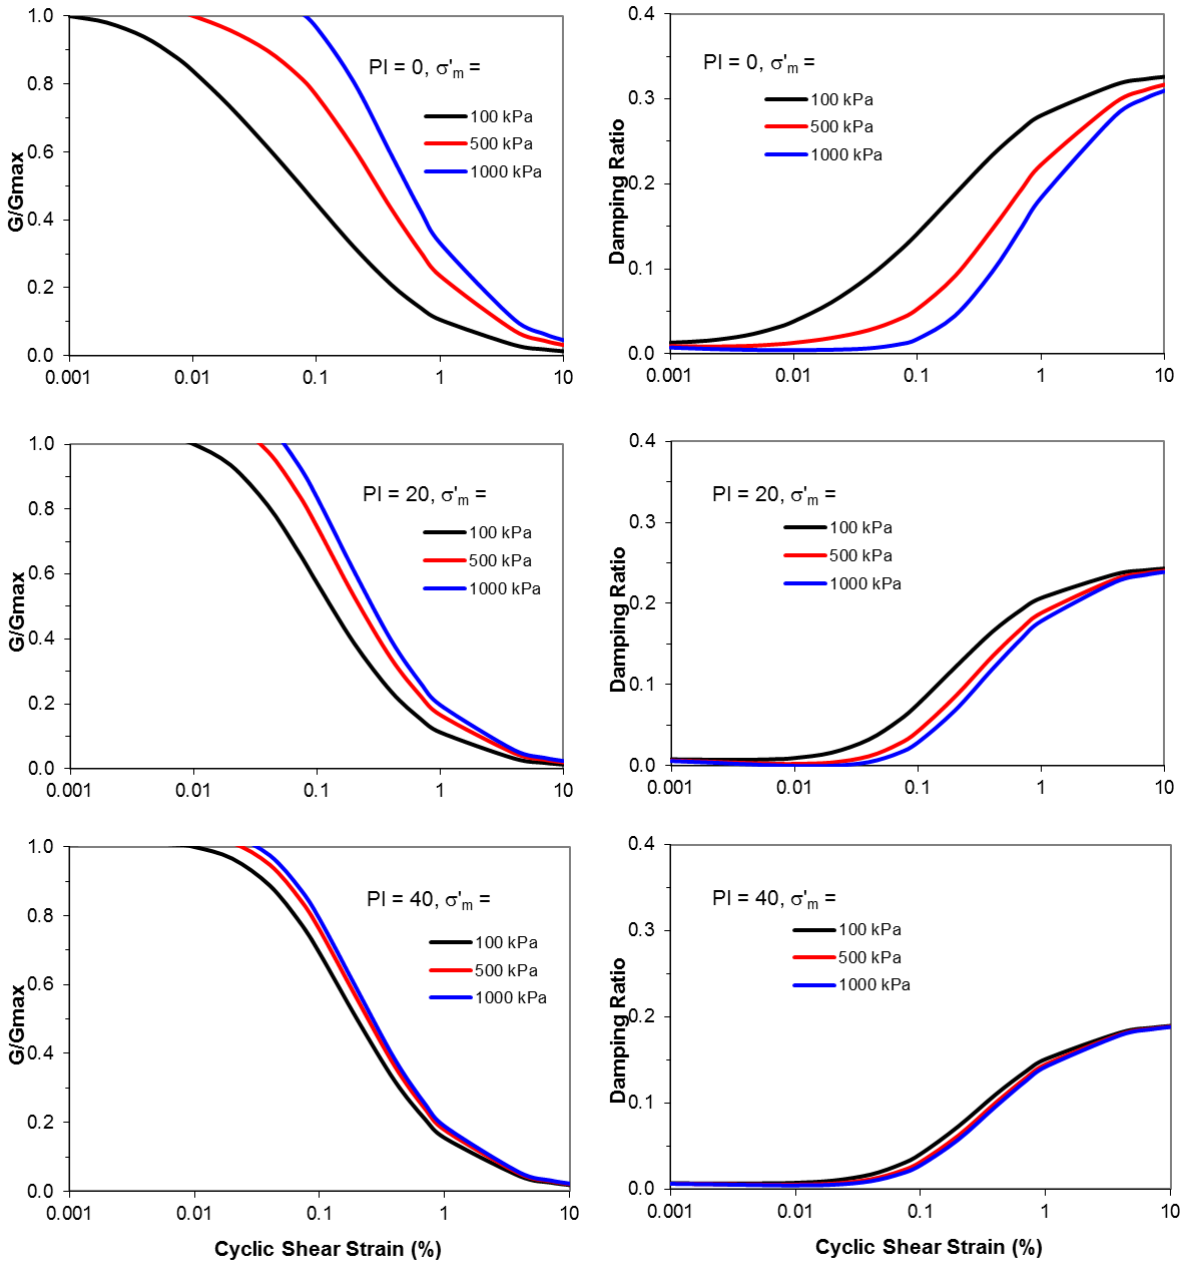

Figure 2. Normalized Shear Modulus (G/G_{max}) Reduction Curves Computed using the Empirical Equations from Ishibashi and Zhang (1993)

2.3. MODULUS REDUCTION AND DAMPING FOR ROCK

The ground response analysis models the propagation of seismic motions through a substantial thickness of “soft rock” and “firm rock”, above the hard basement rock (Section 2.4). Seismologists commonly define hard rock as material with a shear-wave velocity of 9,200 ft/sec or greater. However, for the purposes of this project:

- Hard rock is defined as rock having shear wave velocities of 8,000 ft/sec or greater.
- Firm rock is defined as rock having shear wave velocities between 3,000 and 8,000 ft/sec.
- Soft rock is defined as rock, weathered rock, and/or saprolite having shear wave velocities of 3,000 ft/sec or less.

Consistent with TVA (2016), firm rock and hard rock are modeled as linear elastic materials, with G/G_{max} = 1.0 at all strain levels. A constant damping ratio of 0.50% is assumed for firm and hard rock. This degree of damping is judged to be in a reasonable range for CENA geology, when compared to guidance from EPRI (2012).

The dynamic response of the soft rock is modeled using published modulus reduction and damping relationships developed by Silva et al. (1996), as presented in Stewart et al. (2008). These curves are plotted in Figure 3.

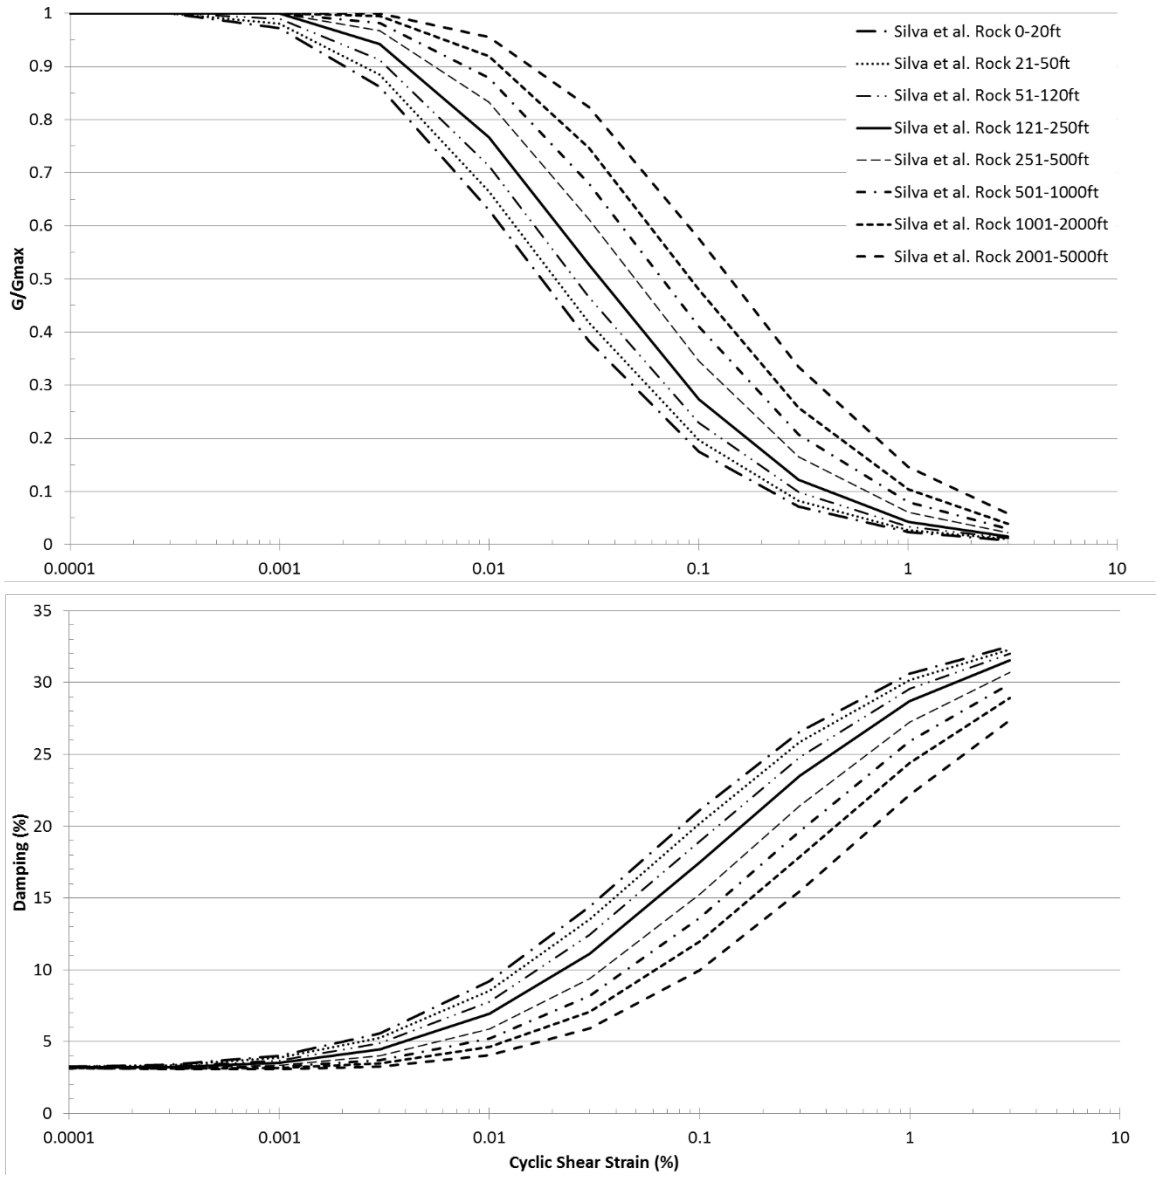

Figure 3. Normalized Shear Modulus (G/G_{max}) Reduction Curves for Soft Rock from Silva et al. (1996), as presented in Stewart et al. (2008)

2.4. PROFILES ANALYZED

In the ground response analysis, the acceleration time histories at the top of bedrock (top of firm rock) and top of ground surface are predicted. A Strata analysis is used to model the propagation of the

earthquake motion from the top of hard basement rock, through the firm rock and soil column at the site. Specifics include:

- The input acceleration time histories are treated as the earthquake motions of a rock outcrop; transfer functions are applied to obtain the corresponding motion within the rock profile, at the top of hard rock.

- The input motions are applied at the top elevation of hard rock, as defined in Section 2.1.

- For deep geologic strata that were not encountered in the geotechnical exploration program, site-specific cross sections prepared by Hatcher (2016) were used. Hatcher's report presents deep structural geology and typical values of shear wave velocity down to the Precambrian basement for multiple TVA dam sites. However, for shallow strata that were encountered in the geotechnical exploration, preference was given to the field data for thickness and shear wave velocity.

- The analysis models the upward propagation of the ground motions through the sequence of rock layers, to the top of bedrock beneath the site.

- The firm rock is modeled as an elastic material with low damping, while soft rock is modeled with non-linear modulus reduction and damping (see Section 2.3). For a particular structure, the firm rock and soft rock column is identical for each profile.

- Each profile includes a representative soil column, suitable for the particular location (top, mid-slope, etc.). Refer to Section 2.2 for the modulus reduction and damping parameters for soil.

- Liquefaction and/or cyclic softening are not modeled in the analysis, so that results represent the ground motions that would occur in the absence of triggering.

- In firm rock, a maximum layer thickness of 100 feet was used. In soft rock and soil, a maximum layer thickness of one-quarter of the wavelength of interest was used. The wavelength of interest is equal to the shear wave velocity divided by the cutoff frequency (taken as 100 Hz for this project). The materials modeled with non-linear behavior require much thinner layering to adequately propagate the ground motions and yield representative results.

The ground response analyses are completed for the subsurface profiles at specific locations (cross section and offsets), as needed to support the pseudostatic, liquefaction, and seismic deformation analyses. These locations are indicated in Table 1.

2.5. GROUND RESPONSE OUTPUTS

Results from the ground response analyses are needed as input for liquefaction analyses and seismic deformation analyses. Table 1 summarizes the location of the profiles, the input ground motions, and the results that are recorded for each analysis. The last row indicates what results are carried forward for input to the subsequent seismic analysis.

For the liquefaction analyses (Section 3), the peak horizontal acceleration at the ground surface (a_{max}) is needed for each analyzed profile. For a given scenario earthquake, both horizontal components of each acceleration time history are analyzed using Strata. The results are plotted to examine the profiles of predicted peak acceleration over the depth of the soil/rock column. The maximum (or mean, depending on the number of time histories considered; see Section 2.1) of the predicted horizontal accelerations at

the ground surface is then selected as a_{max}, with a different value of a_{max} for each profile and scenario earthquake. In the liquefaction analysis, a_{max} is used to compute the Cyclic Stress Ratio (CSR, Section 3.2.2) at each SPT or CPT data point.

For the seismic deformation analyses (Section 4.2), acceleration time histories are recorded at specific elevations in the analyzed profile. These acceleration time histories correspond to the accelerations of the overburden above the slip surface, which are equal to the shear stress time histories at the location of the slip surface divided by the overburden pressure (total vertical stress). The time history elevations correspond to the intersection of the soil profile with the slip surface being evaluated. These time histories are needed for each of the available hard rock ground motions (using both horizontal components of each motion), for each scenario earthquake.

Table 1. Ground Response Analyses to Support other Seismic Analyses

	Liquefaction Triggering	Seismic Deformation
Location of Soil/Rock Profiles Analyzed:	Offsets such as crest, mid-slope, toe, etc., corresponding to groups of SPT or CPT profiles	Offsets corresponding to the top, middle, and bottom of the critical slide mass
Input Ground Motions:	Both horizontal components of each provided hard rock ground motion	Both horizontal components of each provided hard rock ground motion
Recorded Numerical Results:	Peak horizontal acceleration at the ground surface	Time histories of shear stress along slip surface of interest
Results Used in Further Analysis:	Peak horizontal acceleration at ground surface, for each scenario earthquake	Average, horizontal equivalent acceleration for each time history

3. LIQUEFACTION ANALYSIS

Quantitative methods for evaluating whether or not a soil deposit will liquefy during an earthquake (liquefaction triggering analyses) are presented in this section. The resistance to liquefaction or cyclic softening in different soil types (sands to clays) is considered. The methods discussed were developed using empirical data on the performance of similar materials in past earthquakes.

3.1. INITIAL SCREENING FOR SOIL BEHAVIOR

3.1.1. Effect of Soil Fines on Liquefaction Susceptibility

Liquefaction is usually associated with sandy soils, including clean sands and silty sands. The fines content (percent passing the No. 200 sieve) of sandy soils can have a significant impact on liquefaction susceptibility. At the same in situ penetration resistance, liquefaction resistance increases as the fines content of a soil increases. For silty sands, “clean-sand equivalent” SPT blowcounts (Section 3.2.5) or CPT tip resistances (Section 3.2.7) are computed in the assessment methodology. These adjustments for fines content account for the differences observed in the field data base for sands having between about 5 and 35% fines.

While less common, some silts and clays (fine-grained soils with more than 50% fines) have been observed to “liquefy” in large earthquakes. The generation of excess pore pressures under dynamic load leads to significant strength loss and may, depending on the shear stress, result in large ground deformations. For fine grained soils, this behavior is identified as cyclic softening.

The assessment of potential soil liquefaction or cyclic softening is completed in steps:

- For fine-grained soils, index properties are used to identify the behavior as either “sand-like” or “clay-like” (Section 3.1.2).
- For coarse soils (less than about 20% fines) and other “sand-like” soils, the factor of safety against liquefaction is computed using in situ penetration resistance (Section 3.2).
- For “clay-like” fine-grained soils, additional screening criteria are applied to determine if the soil might be susceptible to cyclic softening (Section 3.3.1).
- For “clay-like” soils that are susceptible, the factor of safety against cyclic softening is computed based on the undrained shear strength (Section 3.3.2).

3.1.2. Sand-Like versus Clay-Like Soils

“Sand-like” soils are subject to liquefaction and can be evaluated using a simplified stress-based approach (Sections 3.2), while “clay-like” soils should be evaluated further for cyclic softening (Section 3.3). Various guidance criteria have been proposed for separating soil behavior with respect to cyclic loading, liquefaction, and stress-strain response:

(1) Seed et al. (2003) proposed considering the fines content, liquid limit, plasticity index, and natural water content with respect to Figure 4.

- "Sand-like" soils fall in Zone A on Figure 4. Further, if these soils also meet the water content and fines content requirements indicated, they should be considered potentially liquefiable.
- "Clay-like" soils fall in Zone B on Figure 4. Further, if these soils also meet the water content and fines content requirements indicated, they should be considered susceptible to cyclic softening.
- Soils that fall in Zone C (i.e., anywhere else on the chart) are not usually subject to liquefaction or cyclic softening.

(2) Idriss and Boulanger (2008) offer the following screening criteria based on Atterberg limits:

- "Sand-like" soils have Plasticity Index (PI) < 7.
- "Clay-like" soils have PI ≥ 7.
- Some soils with PI between 3 and 7 could be clay-like, but should be treated as liquefiable (sand-like), unless stress-strain behavior from laboratory testing indicates otherwise.

(3) Design guidance for coal refuse facilities (D'Appolonia Engineering 2010), published by the U.S. Mine Safety and Health Administration (MSHA), suggests differentiating sand-like and clay-like behavior as follows:

- "Sand-like" soils have Plasticity Index (PI) ≤ 7
- "Clay-like" soils have (all three criteria must be satisfied):
  - Percent finer than the No. 40 sieve ≥ 35%
  - Percent finer than the No. 200 sieve ≥ 20%
  - Plasticity Index (PI) ≥ 10
- Borderline soils should be treated as sand-like, unless stress-strain behavior from laboratory testing indicates otherwise. The MSHA guidance document suggests:
  - Loose or soft material with a shear strain less than 2 percent at the peak strength in an undrained monotonic test, and a rapid drop-off in the post-peak shearing resistance, should be considered sand-like.
  - Loose or soft material with a shear strain more than about 5 percent at the peak strength in an undrained monotonic test, and a gradual drop-off in the post-peak shearing resistance, may be considered clay-like.

The three sets of guidance criteria presented above may provide conflicting indications of behavior under dynamic load. All of these criteria are used together, with engineering judgment, to determine if a particular soil stratum is subject to liquefaction or cyclic softening.

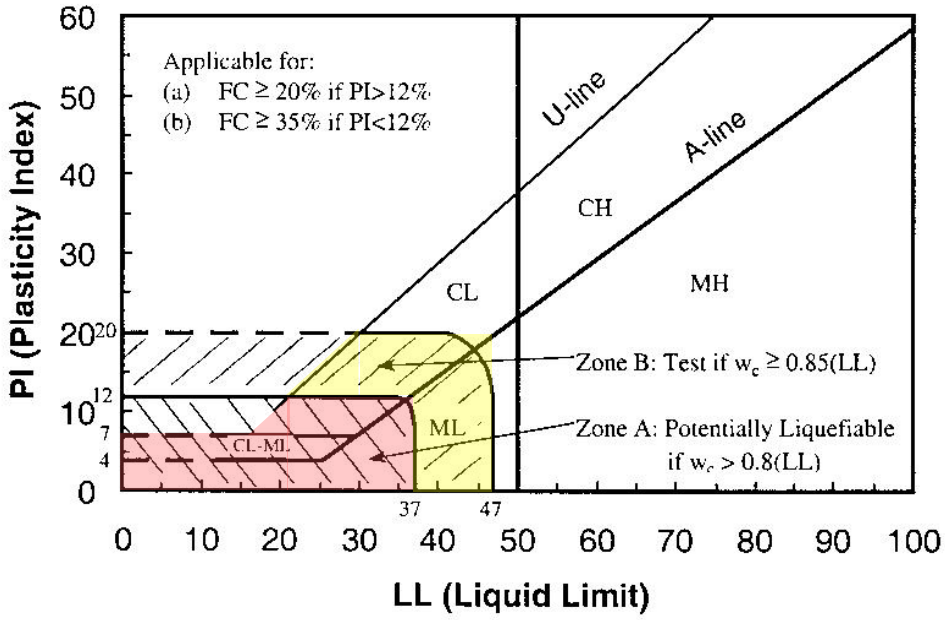

Figure 4. Example of Criteria for Assessing Liquefaction or Cyclic Softening in Fine Grained Soils (after Seed et al. 2003)

3.2. LIQUEFACTION OF SAND-LIKE SOILS

Seed and Idriss (1971) proposed a simplified, empirical procedure for evaluating liquefaction potential of sands based on in situ penetration resistance (indicative of relative density), initial confining stress, and intensity of ground shaking. This methodology has undergone continued development and refinement since its initial inception. The procedures were evaluated in detail and summarized by a workshop of experts organized by the National Center for Earthquake Engineering Research (NCEER) (Youd and Idriss 1997). They updated details of the liquefaction assessment method, which is now often referred to as the "NCEER Method" (Youd et al. 2001). The National Academies (2016) refers to this method as a "simplified stress-based approach"; this term will be used within this document.

In recent years, various researchers have published variations or updates to the simplified stress-based approach. Often these updates relate to the case histories that serve as the basis for correlating in situ penetration resistance to the potential for liquefaction triggering. New case histories (documentation of sites that did or did not liquefy due to an earthquake) may be added and/or previously published case histories may be reinterpreted. The National Academies (2016) report emphasizes the importance of

implementing such methods in a manner consistent with how they were developed. Analysts should avoid using techniques and adjustment factors from one variant of the method with other variants.

The approach below is based on methodology of Idriss and Boulanger (2008), with updates per Boulanger and Idriss (2014; 2016). This provides an approach that is internally consistent and generally accepted per the current state of the practice.

3.2.1. Factor of Safety for Liquefaction

The liquefaction resistance of a soil is evaluated in terms of a cyclic resistance ratio (CRR), and the load induced by the earthquake is quantified using a cyclic stress ratio (CSR). Both the CRR and CSR represent a shear stress normalized with respect to the vertical effective stress in the soil. The factor of safety against liquefaction (FS_{liq}) is then computed by taking the ratio of CRR over CSR:

$$FS_{liq} = \frac{CRR}{CSR} \qquad \textbf{Equation 13}$$

Details for the computation of CRR and CSR, as implemented in spreadsheet calculations, are described below.

Unsaturated soils do not liquefy. The factor of safety against liquefaction is thus assumed to be very high (although numerically undefined) in soils above the phreatic surface.

3.2.2. Cyclic Stress Ratio

The cyclic stress ratio (CSR) is the average cyclic shear stress induced by the earthquake, at a particular location in the soil, normalized with respect to the vertical effective stress (σ'_v). The average shear stress at a point in the soil profile is assumed to be 65% of the maximum induced cyclic shear stress ($\tau_{cyc,max}$) (Seed and Idriss 1971):

$$CSR = 0.65 \cdot \frac{\tau_{cyc,max}}{\sigma'_v} \qquad \textbf{Equation 14}$$

CSR values can be computed directly from the maximum shear stress predicted with ground response analyses. However, CSR is often computed using a simplified equation originally developed by Seed and Idriss (1971). They computed CSR based on the peak acceleration at the ground surface (a_{max}, expressed as a fraction of gravity) and a stress reduction factor (r_d), which accounts for the dynamic response of the soil profile:

$$CSR = 0.65 \cdot \frac{\sigma_v}{\sigma'_v} \cdot \frac{a_{max}}{g} \cdot r_d \qquad \textbf{Equation 15}$$

Boulanger and Idriss (2016) acknowledge that the maximum shear stress can be computed directly from ground response analyses, instead of using the simplified approach based on a_{max} and r_d. The former approach takes advantage of site-specific (or boring-specific) ground response results (maximum shear

stress versus depth profiles), whereas the latter applies a single value of acceleration (which could be boring-specific) and the published, empirical stress reduction factor.

While using shear stress profiles from site-specific ground response analyses would appear to be more precise, the National Academies (2016) notes that "…the use of site response analysis to estimate the earthquake-induced CSR is appropriate if, and only if, the r_d factors used in the development of the CRR curve are unbiased relative to the values expected at liquefaction sites." In the event that "biased" methods are employed, "…the results of site response analyses should be used only to refine the estimate of the PGA at the ground surface [a_{max}]." In this context, the procedure developed by Idriss and Boulanger (2008) is considered a biased method. Using site-specific ground response to directly compute induced shear stresses can introduce "…additional and unquantifiable uncertainty into the liquefaction assessment."

Therefore, site-specific ground response analyses are used to obtain a_{max} at the ground surface. To quantify the CSR at depth, the r_d factor from Boulanger and Idriss (2016) is used:

$$r_d = \exp\left[\alpha(z) + \beta(z) \cdot M\right] \qquad \textbf{Equation 16}$$

$$\alpha(z) = -1.012 - 1.126 \cdot \sin\left(\frac{z}{11.73} + 5.133\right)$$

$$\beta(z) = 0.106 + 0.118 \cdot \sin\left(\frac{z}{11.28} + 5.142\right)$$

Where z is the depth below the ground surface in meters, the arguments inside the sin terms are in radians, and M is the moment magnitude of the earthquake.

CSR values are computed at each SPT or CPT data point, to match the calculation of CRR (Section 3.2.3). The value of a_{max} is taken from the ground response analyses for the various ground motions considered (Section 2.5). The ground response analyses are defined for groups of borings with similar conditions (for example, one analysis may represent multiple borings).

3.2.3. Cyclic Resistance Ratio for Sand-Like Soils

The cyclic resistance ratio (CRR) is the average cyclic shear stress that would cause liquefaction, divided by the vertical effective stress at that location. Using the field performance correlations, CRR is estimated conservatively based on in situ penetration resistance (SPT blowcounts or CPT tip stress).

As discussed in this section, the CRR for a M = 7.5 earthquake ($CRR_{7.5}$) is computed from the clean-sand equivalent, normalized SPT blowcount or CPT tip resistance [$(N_1)_{60CS}$ or $(q_{c1N})_{cs}$]. To account for other earthquake magnitudes, $CRR_{7.5}$ is modified using a magnitude scaling factor (MSF). Adjustments are also made to account for high overburden pressures (K_σ) and static driving shear stresses (K_α). The CRR is then computed as:

$$CRR = CRR_{7.5} \cdot MSF \cdot K_\sigma \cdot K_\alpha \qquad \textbf{Equation 17}$$

The correction factors MSF, K_σ, and K_α are discussed below in Sections 3.2.8, 3.2.9, and 3.2.10, respectively.

When using SPT blowcounts, the field measurements of N_{SPT} are first adjusted and corrected to account for variations in the field test procedures, equipment, and fines content as discussed in Section 3.2.4. $CRR_{7.5}$ is then estimated from the $(N_1)_{60CS}$ using the bounding curve in Figure 5. For values of $(N_1)_{60\text{-}CS}$ less than about 32, the following equation is used for the base curve (Idriss and Boulanger 2008; Boulanger and Idriss 2014):

$$CRR_{7.5} = \exp\left(\frac{(N_1)_{60CS}}{14.1} + \left(\frac{(N_1)_{60CS}}{126}\right)^2 - \left(\frac{(N_1)_{60CS}}{23.6}\right)^3 + \left(\frac{(N_1)_{60CS}}{25.4}\right)^4 - 2.8\right) \qquad \textbf{Equation 18}$$

For values of $(N_1)_{60\text{-}CS}$ greater than or equal to about 32, clean granular soils are considered too dense to liquefy and are classified as unliquefiable.

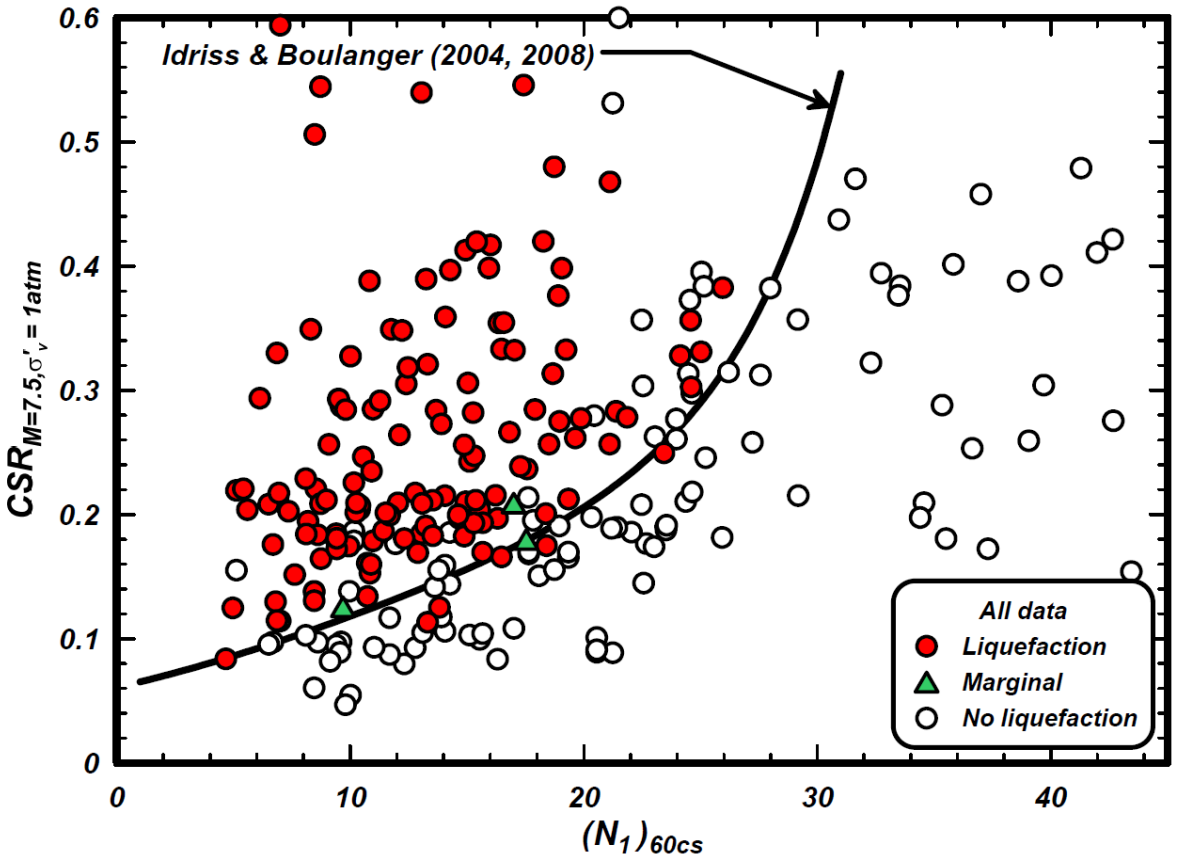

Figure 5. Field data and empirical relationship between liquefaction resistance and corrected SPT blowcount (Boulanger and Idriss 2014).

The value of $CRR_{7.5}$ can also be computed from the measured CPT tip resistance and the field performance correlation in Figure 6 (Boulanger and Idriss 2014; 2016). Field measurements of CPT tip stress are first normalized and adjusted to account for the effects of overburden pressure and fines content, as described in Section 3.2.6. The remaining calculation procedure uses the parameter q_{c1Ncs}, which is the computed clean-sand equivalent penetration resistance normalized to one atmosphere of overburden pressure. The following equations represent the CPT-based clean sand base curve for the correlation shown in Figure 6, and can be used to compute $CRR_{7.5}$:

$$CRR_{7.5} = \exp\left(\frac{q_{c1Ncs}}{113} + \left(\frac{q_{c1Ncs}}{1000}\right)^2 - \left(\frac{q_{c1Ncs}}{140}\right)^3 + \left(\frac{q_{c1Ncs}}{137}\right)^4 - 2.80\right) \qquad \textbf{Equation 19}$$

For values of q_{c1Ncs} greater than or equal to about 175, clean granular soils are considered too dense to liquefy and are classified as unliquefiable.

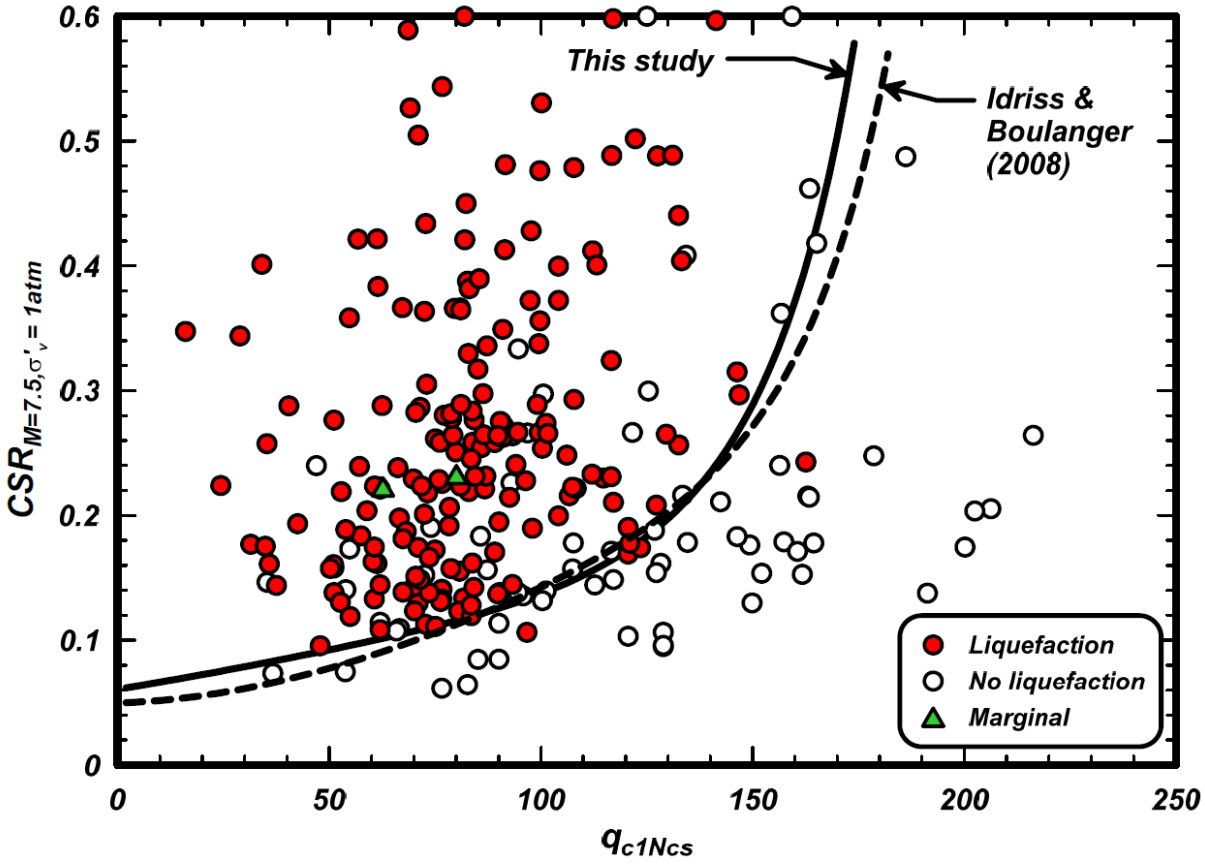

Figure 6. Field data and empirical relationship between liquefaction resistance and corrected CPT tip resistance (Boulanger and Idriss 2014).

3.2.4. Corrected Standard Penetration Test Blowcounts

The field-measured Standard Penetration Test (SPT) blowcounts (N_{SPT} values) are corrected as needed for use in various parameter correlations and analyses. As described in the SEDR, hammer energy calibrations were performed for each drill rig used at the site; the subsequent data were used to correct the SPT N-values. N-values were also normalized and corrected for overburden pressures, rod length, borehole diameter, and sampler type. The corrected blow counts are presented in Exhibit D.2.

3.2.4.1. SPT Blowcount Correction for Drilling and Sampling Techniques

The N_{SPT} values must be corrected, adjusted, and/or normalized to account for the effects of hammer energy, borehole diameter, length of drill rods, and nonstandard samplers. This results in "corrected" blowcounts (N_{60}). Corrected blowcounts are used for liquefaction analyses, but they can also be correlated to other engineering properties. The methodology described below to derive N_{60} is consistent with Idriss and Boulanger (2008). Further normalization to correct for overburden stress ($(N_1)_{60}$) and fines content ($(N_1)_{60CS}$) is specific to liquefaction triggering analyses, and is discussed in Sections 3.2.4.2 and 3.2.5, respectively.

The corrected blowcount, N_{60}, is computed as:

$$N_{60} = N_{SPT} \cdot C_E \cdot C_B \cdot C_R \cdot C_S \qquad \textbf{Equation 20}$$

The correction parameters C_E, C_B, C_R, and C_S are defined as follows.

C_E corrects N_{SPT} for differences in SPT hammer energy, using as a standard reference a hammer that delivers 60% of the maximum theoretical energy (2.5-foot drop x 140-lbs = 350 foot-lbs per blow). Defining the hammer efficiency, or energy ratio (ER), as the actual energy delivered by the SPT hammer over the maximum theoretical energy, the value of C_E is then:

$$C_E = \frac{ER}{60\%} \qquad \textbf{Equation 21}$$

Typical ranges for two common hammer types are given in Table 2. Here, the SPT hammer energy was measured directly during the field explorations, using instrumentation mounted at the top of the drill rods, to determine C_E factors specific to the equipment and site conditions. Energy measurements were made in selected borings at the site, and the hammer efficiency measured for a particular hammer is assumed representative of the energy imparted with the same equipment at other, similar borings at the site.

Table 2. Typical Correction Factors for SPT Hammer Energy (Youd et al. 2001; Idriss and Boulanger 2008)

Hammer Type	ER	C_E
Safety Hammer	42 to 72%	0.7 to 1.2
Automatic-Trip (Donut) Hammer	48 to 78%	0.8 to 1.3

C_B corrects for the influence of borehole diameter on the measured blowcount. The effect is related to the surface area of the exposed soil at the bottom of the borehole, relative to the size of the standard sampler. The borehole diameter is assumed equal to the internal diameter of the casing or hollow stem auger, if used. Recommended values are given in Table 3(a). To apply this correction without sharp jumps in C_B for small differences in diameter, the values in Table 3(a) are linearly interpolated for diameters in the range of 4.5 to 8 inches, as presented in Table 3(b).

Table 3. Correction Factors for Borehole Diameter

Inner Diameter (ID) of Borehole, Casing, or Auger (inches)	C_B
(a) Typical values (Skempton 1986; Idriss and Boulanger 2008)	
2.5 to 4.5	1.00
6	1.05
8	1.15
(b) Interpolated values	
$ID \leq 4.5$	$C_B = 1.00$
$4.5 < ID \leq 6$	$C_B = (ID/30) + 0.85$
$6 < ID \leq 8$	$C_B = (ID/20) + 0.75$
$8 < ID$	$C_B = 1.15$

C_R corrects for energy losses in short drilling rods, due to reflections of energy from the bottom of the drill stem. Values of the rod length correction factor (Table 4) were recommended by Youd et al. (2001) and Idriss and Boulanger (2008). In applying the C_R correction, the length of drill rod is assumed to equal the depth to the sampling location, plus 5 feet to account for the typical length of drill rod sticking up above the ground surface. For deeper sample locations (rod lengths exceeding 30 m), no correction is applied ($C_R = 1.0$).

The values of C_R in Table 4 are based on the work of Schmertmann and Palacios (1979). Due to limitations in the instrumentation available at the time of their work, Schmertmann and Palacios were unable to accurately measure accelerations in the drill rod after each impact. They measured hammer energy using the "F^2" method and proposed the rod-length correction based on theoretical considerations

of wave propagation. With modern instrumentation, the delivered hammer energy can be measured using the "Fv" method. This provides a more reliable measure of hammer energy (Butler et al. 1998) and obviates the need to make corrections for short rods (personal communications, Frank Rausche, April 15, 2005, and Ray B. Seed, April 20, 2005). Daniel et al. (2005) point out the need for more research on this question. Sancio and Bray (2005) concluded that short rod lengths have only a small effect on ER when measured using the "Fv" method.

Additional insights into the application of C_R are provided by Youd et al. (2001):

> "*Although application of rod-length correction factors will give more precise $(N_1)_{60}$ values, these corrections may be neglected for liquefaction resistance calculations for rod lengths between 3 and 10 m because rod-length corrections were not applied to SPT test data from these depths in compiling the original liquefaction case history databases. Thus, rod-length corrections are implicitly incorporated into the empirical SPT procedure.*"

Because the hammer energy is measured using the "Fv" method and the C_E is based on those field measurements, the C_R correction factor is *not* applied here to the SPT blowcounts (C_R = 1.0 is used in the calculations).

Table 4. Correction Factors for Energy Losses in the Drill Rods (Youd et al. 2001; Idriss and Boulanger 2008)

Length of Drill Rod (m)	Length of Drill Rod (feet)	C_R
< 3	< 10	0.75
3 to 4	10 to 13	0.8
4 to 6	13 to 20	0.85
6 to 10	20 to 33	0.95
10 to 30	33 to 100	1.0

Split-spoon samplers are often designed to hold an internal tube, or liner, for containing the retrieved soil sample. However, the split spoons are often used without the liners in place, thereby reducing the interior friction as the sampler is advanced (the inside diameter of the sampler is greater than that of the driving shoe). To account for this effect, the C_S correction factor is applied when a sampler is used without the liners. Recommended values are shown in Table 5. When liners are not used, the correction ranges from 10 to 30 percent, and increases linearly as the blowcount increases. Here, samplers were used without the liners and the correction in Table 5 is applied. Note that the value of C_S is a function of $(N_1)_{60}$ (Section 3.2.4.2), which requires an iterative/trial solution scheme to determine the sampler correction factor for a given SPT blowcount.

Table 5. Correction Factors for Non-Standard Split-Spoon Samplers (Seed et al. 2001; Idriss and Boulanger 2008)

Sampler	C_S
Standard sampler with liners	1.0
Standard sampler without liners	$1.1 \leq (1+(N_1)_{60}/100) \leq 1.3$

3.2.4.2. SPT Blowcount Correction for Overburden Stress

Section 3.2.4.1 documents correction of field-measured Standard Penetration Test (SPT) blowcounts (N_{SPT}) for the effects of hammer energy, borehole diameter, length of drill rods, and nonstandard samplers. The result is designated N_{60}. For liquefaction triggering analysis, blowcounts are also normalized to a standard, effective overburden stress of one atmosphere. The overburden correction factor is designated C_N and the resulting normalized blowcount is designated $(N_1)_{60}$.

$$(N_1)_{60} = C_N \cdot N_{60} \qquad \textbf{Equation 22}$$

The C_N correction factor from Boulanger and Idriss (2014) is used in this analysis and is shown graphically in Figure 7.

$$C_N = \left(\frac{P_a}{\sigma'_v}\right)^{0.784-0.0768\sqrt{(N_1)_{60CS}}} \leq 1.7 \qquad \textbf{Equation 23}$$

Here, σ'_v is the vertical effective stress at the depth of $(N_1)_{60CS}$ and P_a is one atmosphere (atm) of pressure in the units of σ'_v (P_a = 14.69 psi = 2,116 psf = 101.3 kPa). This expression of C_N is limited to $(N_1)_{60CS}$ values less than or equal to 46 (Boulanger and Idriss 2014). Also, at low effective stresses (σ'_v less than about 0.35 atm), C_N is limited to 1.7 to avoid excessively large adjustments at shallow depths. The correction factor is not defined for effective stresses greater than 10 atmospheres, but the curves in Figure 7 are approaching an asymptote at this limit. Note that the value of C_N is a function of $(N_1)_{60CS}$ (Section 3.2.5), which requires an iterative/trial solution scheme to determine the overburden correction factor for a given SPT blowcount.

Note that labels on plots should read "$(N_1)_{60CS}$" and "q_{c1Ncs}" instead of "$(N_1)_{60}$" and "q_{c1N}".

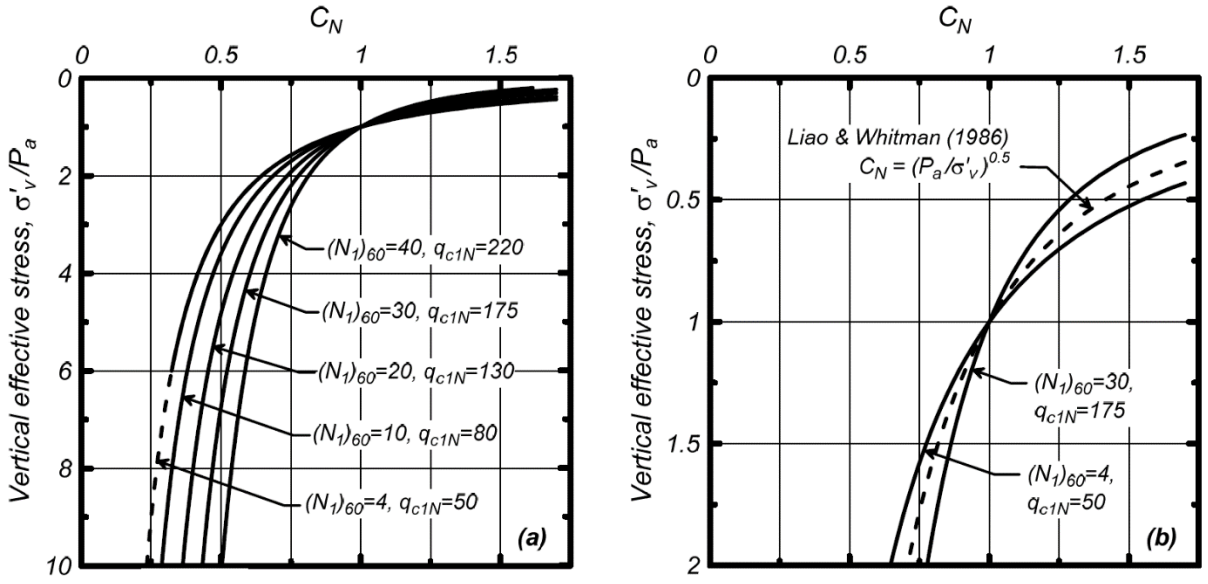

Figure 7. Correction Factor for Overburden Stress (Boulanger and Idriss 2014).

3.2.5. Clean-Sand Equivalent SPT Blowcounts

The liquefaction triggering potential of sand-like soils varies with fines content. The simplified stress-based approach includes an adjustment in $(N_1)_{60}$ to account for the fines content. The "clean-sand equivalent blowcount", $(N_1)_{60CS}$, is computed per Boulanger and Idriss (2014) as:

$$(N_1)_{60CS} = (N_1)_{60} + \Delta(N_1)_{60} \qquad \textbf{Equation 24}$$

$$\Delta(N_1)_{60} = \exp\left(1.63 + \frac{9.7}{FC + 0.01} - \left(\frac{15.7}{FC + 0.01}\right)^2\right)$$

where FC is the fines content in percent (percent by weight passing the No. 200 sieve, value ranging from 0 to 100). The adjustment (Figure 8) approaches a fairly constant value for FC values exceeding about 35% because the soil matrix becomes fines-dominated (Boulanger and Idriss 2014).

The adjustment from $(N_1)_{60}$ to $(N_1)_{60CS}$ was developed using data on liquefaction resistance. Hence, $(N_1)_{60CS}$ reflects both the increase in liquefaction resistance and decrease in penetration resistance due to a fines content greater than about 5 percent (Youd et al. 2001).

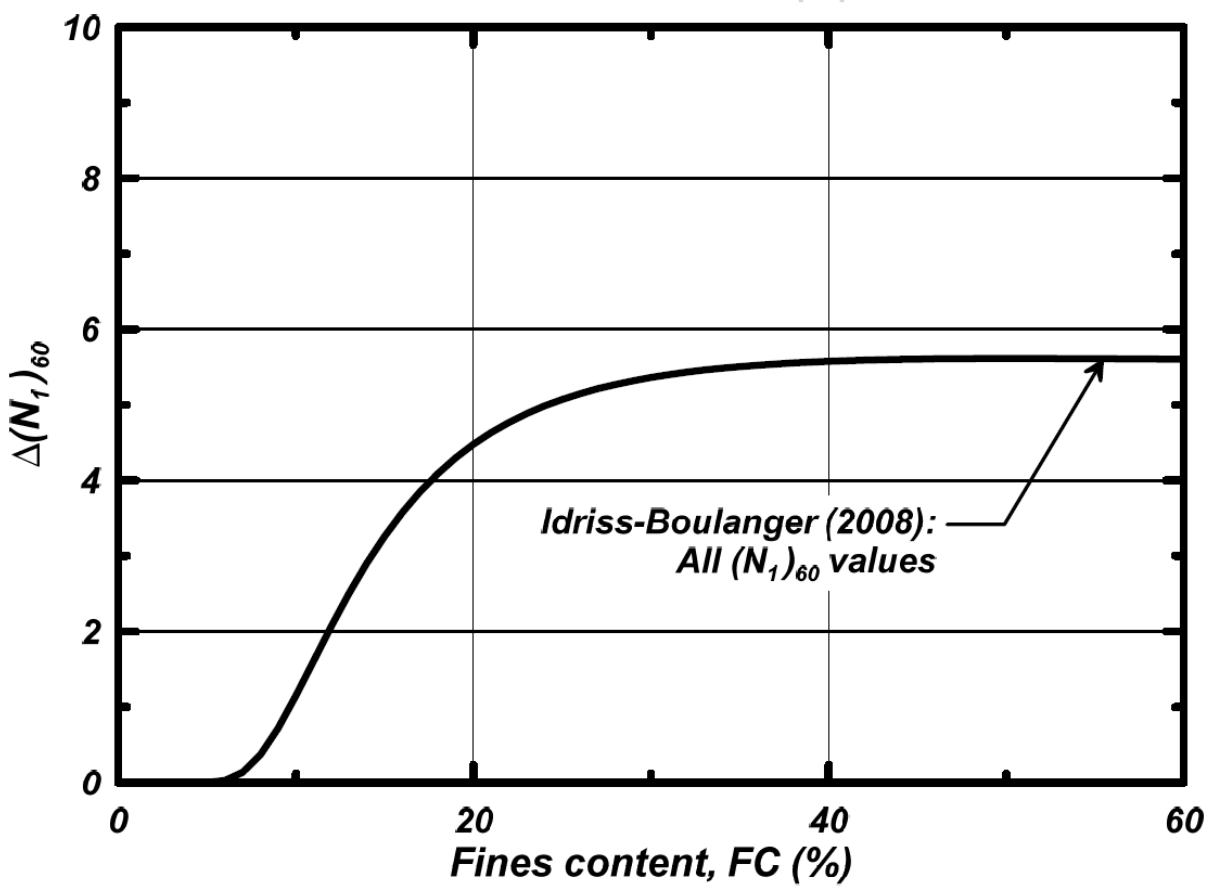

Figure 8. Equivalent clean sand adjustment for SPT-based liquefaction triggering procedures (Boulanger and Idriss 2014).

Where the gradation of an individual SPT sample is not directly measured in the laboratory, the calculation of $(N_1)_{60CS}$ must rely on an interpolated or estimated fines content. The fines content associated with a specific N_{SPT} value is thus determined, in decreasing order of preference, as:

- Where SPT samples are subjected to particle size analysis, FC is taken from the laboratory value.
- When the gradation is not measured on a given sample, FC is estimated based on measurements from other samples in the same soil horizon and/or soil boring.
- When no gradation data is available for a given soil horizon, the fines content is assigned based on the USCS classification, assuming the minimum fines content for that soil classification. This

yields a conservative correction (smallest corrected $(N_1)_{60CS}$) for determining liquefaction resistance.

3.2.6. Corrected Cone Penetration Tip Resistance

The measured resistance to penetration of the conical CPT tip (q_c), in units of stress, is recorded as the cone penetrometer probe is advanced into the soil. Due to details of the probe design, pore water pressures acting behind the cone tip affect the measurement of tip resistance. A corrected cone tip resistance (q_t) is computed as:

$$q_t = q_c + (1 - a_r) \cdot u_2 \qquad \textbf{Equation 25}$$

where a_r is the net area ratio and u_2 is the pore water pressure measured just behind the cone tip. The differences between q_c and q_t are usually small in granular soils, while the effect of the correction is more significant in soft, clayey soils where q_c is small and u_2 is large. In some cases, this correction is performed within the data acquisition system, and only q_t is provided in the CPT raw data files. In the referenced methodology (i.e., Boulanger and Idriss 2014; 2016), the term q_c is used in equations, with the understanding that the raw data has been corrected to q_t whenever the u_2 data are available. For consistency, this convention is used in the formulas below.

The tip resistance is corrected for the effects of overburden pressure and normalized to a dimensionless value per Boulanger and Idriss (2016):

$$q_{c1N} = C_N \cdot \frac{q_c}{P_a} \qquad \textbf{Equation 26}$$

where P_a is one atmosphere of pressure in the units of q_c (P_a = 14.69 psi = 2,116 psf = 101.3 kPa). The C_N correction factor from Boulanger and Idriss (2016) is used in this analysis and is shown graphically in Figure 7.

$$C_N = \left(\frac{P_a}{\sigma'_v}\right)^{1.338 - 0.249 \cdot (q_{c1Ncs})^{0.264}} \leq 1.7 \qquad \textbf{Equation 27}$$

Here, σ'_v is the vertical effective stress at the depth of q_{c1Ncs} and P_a is one atmosphere of pressure in the units of σ'_v (P_a = 14.69 psi = 2,116 psf = 101.3 kPa). This expression of C_N is limited to q_{c1Ncs} values between 21 and 254 (Boulanger and Idriss 2016). Also, at low effective stresses (σ'_v less than about 0.35 atm), C_N is limited to 1.7 to avoid excessively large adjustments at shallow depths. The correction factor is not defined for effective stresses greater than 10 atmospheres, but the curves in Figure 7 are approaching an asymptote at this limit. Note that the value of C_N is a function of q_{c1Ncs} (Section 3.2.7), which requires an iterative/trial solution scheme to determine the overburden correction factor for a given CPT tip resistance.

Using CPT data, soil behavior can be classified using the chart in Figure 9 (Robertson 1990; Boulanger and Idriss 2016). The classification is based on a normalized cone resistance (Q):

$$Q = \left(\frac{q_c - \sigma_v}{P_a}\right) \cdot \left(\frac{P_a}{\sigma'_v}\right)^n \qquad \textbf{Equation 28}$$

where the variables are as defined previously, except the exponent n which is defined below. The classification chart also uses the normalized sleeve friction ratio (F):

$$F = \left(\frac{f_s}{q_c - \sigma_v}\right) \cdot 100\% \qquad \textbf{Equation 29}$$

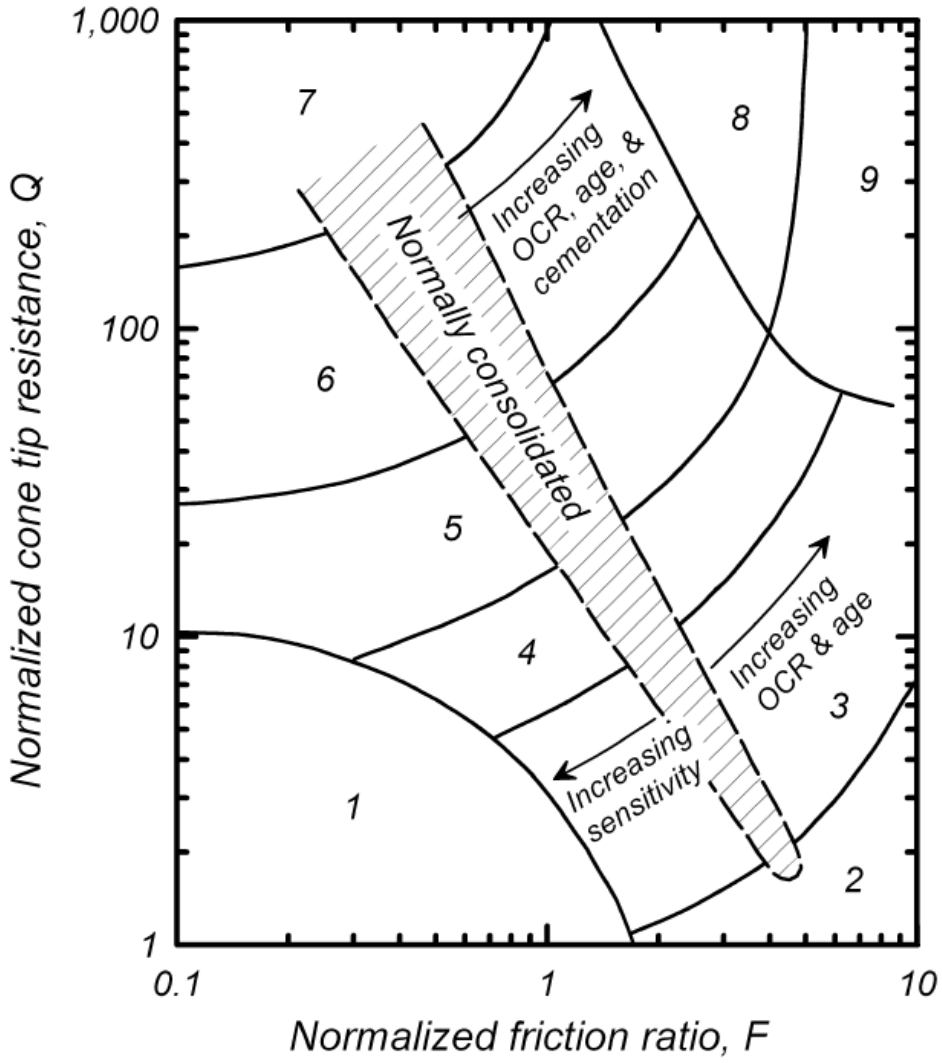
where f_s is the measured sleeve resistance (units of stress). The boundaries between soil types 2 to 7 in Figure 9 can be approximated using concentric circles having radii equal to the soil behavior type index (I_c):

$$I_c = [\,(3.47 - \log(Q))^2 + (1.22 + \log(F))^2\,]^{0.5} \qquad \textbf{Equation 30}$$

The value of the exponent (n) in Equation 28 depends on the soil type, necessitating a three-step iterative solution scheme (Robertson and Wride 1998; Boulanger and Idriss 2016):

- *Step 1*: Assume n = 1.0 (characteristic of clays) and compute I_c. If $I_c > 2.6$, the soil is classified as clayey and n = 1.0 is used. Such soils are typically clay-like.
- *Step 2*: If $I_c < 2.6$ in Step 1, assume n = 0.5 (characteristic of granular soils) and re-compute I_c. If $I_c < 2.6$, then use n = 0.5 to further evaluate sand-like liquefaction resistance.
- *Step 3*: If $I_c > 2.6$ in Step 2, the soil is probably very silty and possibly plastic. In this case, evaluate the liquefaction resistance using an intermediate value of n = 0.7.

In addition, soils with $I_c > 2.6$ and $F < 1\%$ will plot in region 1 of Figure 9; such soils may be very sensitive and should be appropriately evaluated for liquefaction resistance.



1. Sensitive, fine grained
2. Organic soils - peats
3. Clays - silty clay to clay
4. Silt mixtures - clayey silt to silty clay
5. Sand mixtures - silty sand to sandy silt
6. Sands - clean sand to silty sand
7. Gravelly sand to dense sand
8. Very stiff sand to clayey sand *
9. Very stiff, fine grained *

* Heavily overconsidated or cemented

Figure 9. Soil Behavior-Type Chart for Classifying Soils from CPT Data (Boulanger and Idriss 2014, after Robertson 1990).

3.2.7. Clean-Sand Equivalent CPT Tip Resistance

The fines content (percent passing the No. 200 sieve) of a soil can have a significant impact on liquefaction resistance. For sand-like soils with significant fines, the simplified stress-based approach (Boulanger and Idriss 2016) includes the calculation of a “clean-sand equivalent penetration resistance", q_{c1Ncs}:

$$q_{c1Ncs} = q_{c1N} + \Delta q_{c1N} \qquad \textbf{Equation 31}$$

$$\Delta q_{c1N} = \left(11.9 + \frac{q_{c1N}}{14.6}\right) \exp\left(1.63 - \frac{9.7}{FC + 2} - \left(\frac{15.7}{FC + 2}\right)^2\right)$$

where FC is the fines content in percent (percent by weight passing the No. 200 sieve, value ranging from 0 to 100). The adjustment factor is shown in Figure 10.

If sufficient laboratory data or other site-specific information are not available to estimate the fines content, Boulanger and Idriss (2016) provide a correlation of fines content to I_c (Equation 30). Note that such general correlations exhibit large scatter, as shown in Figure 11.

$$FC = 80 \cdot (I_c + C_{FC}) - 137 \qquad \textbf{Equation 32}$$

where the resulting value of FC (in percent) ranges from 0 to 100 and C_{FC} is a fitting parameter. The default value of C_{FC} is zero, but one standard deviation of the data shown in Figure 11 yields C_{FC} of -0.29 to 0.29. If site-specific data are available for calibration, the value of C_{FC} could be adjusted to improve the correlation.

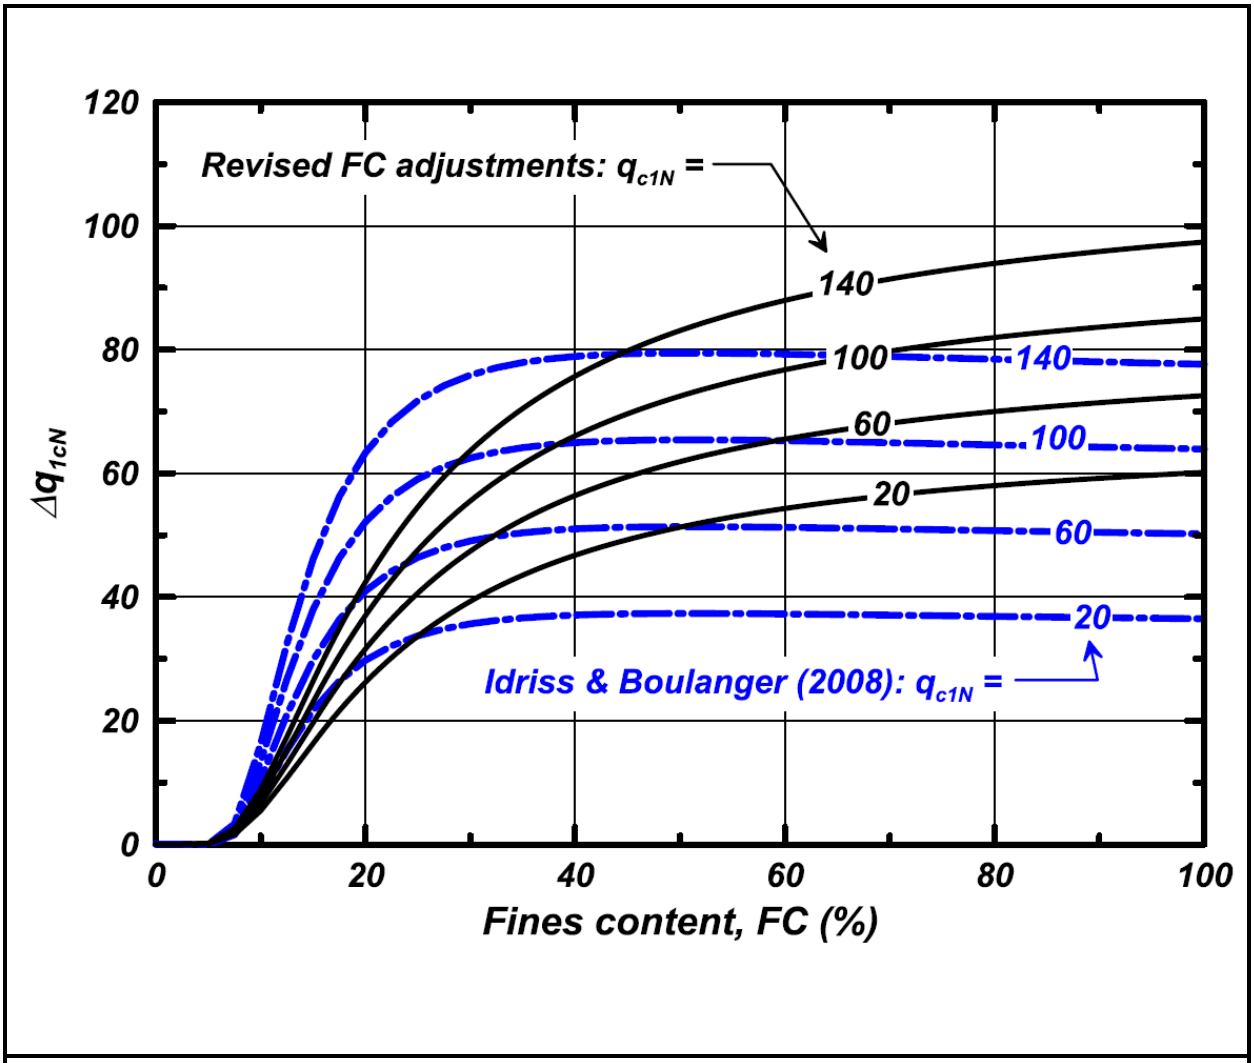


Figure 10. Equivalent clean sand adjustment for CPT-based liquefaction triggering procedures (solid lines per Boulanger and Idriss 2016).

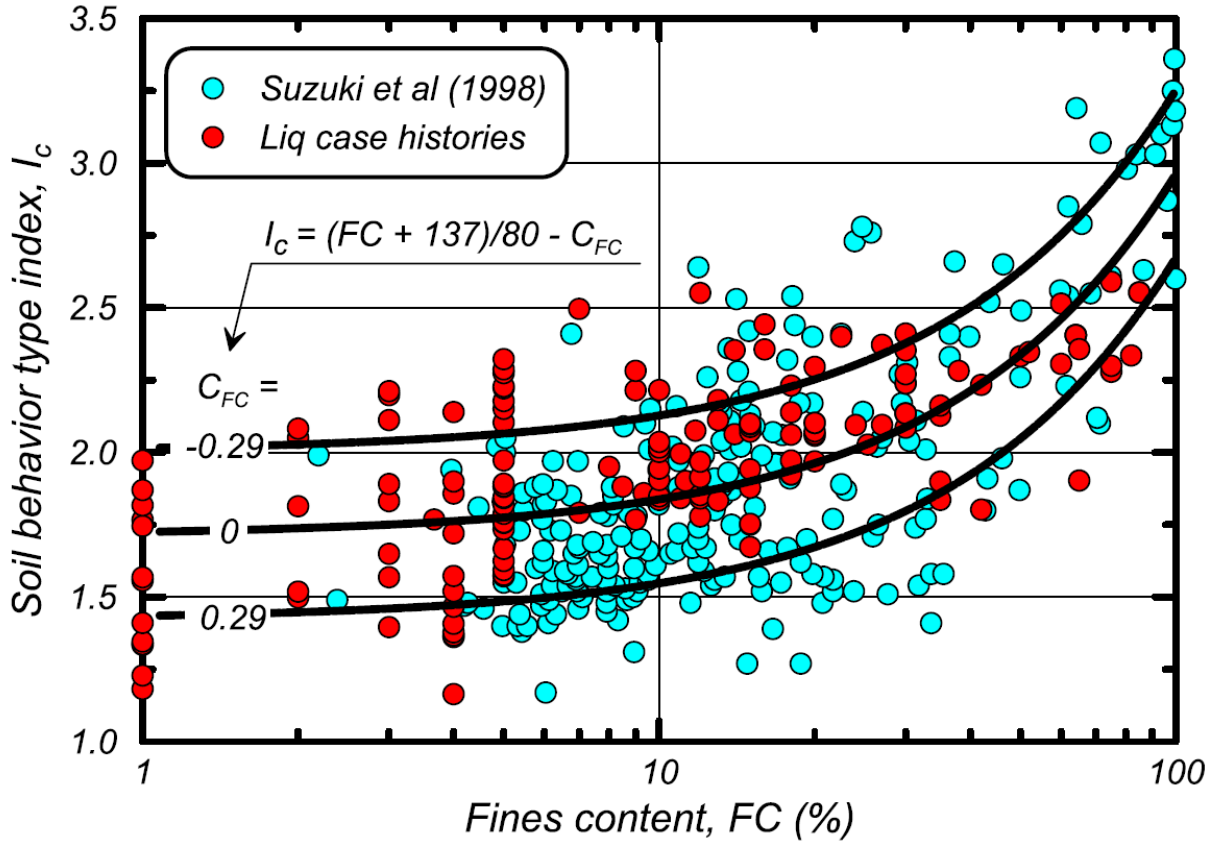

Figure 11. Correlation between I_c and FC (Boulanger and Idriss 2016).

3.2.8. Magnitude Scaling Factor for Sand-Like Soils

The simplified stress-based approach was originally developed using a database of case histories from earthquakes near magnitude 7.5. A magnitude scaling factor (MSF) is applied to the CRR to account for the greater (or lesser) number of significant stress cycles experienced in larger (or smaller) magnitude earthquakes. Boulanger and Idriss (2014; 2016) performed additional studies that indicate MSF is not only a function of earthquake magnitude, but also of soil characteristics. They express this dependency in terms of $(N_1)_{60CS}$ or q_{c1Ncs}, for SPT or CPT based analyses, respectively.

$$MSF = 1 + (MSF_{max} - 1) \cdot \left[8.64 \cdot \exp\left(\frac{-M}{4}\right) - 1.325\right]$$ **Equation 33**

$$MSF_{max} = 1.09 + \left(\frac{(N_1)_{60CS}}{31.5}\right)^2 \leq 2.2$$

$$MSF_{max} = 1.09 + \left(\frac{q_{c1Ncs}}{180}\right)^3 \leq 2.2$$

where M is the moment magnitude of the earthquake. This magnitude scaling factor for the assessment of sand-like soil liquefaction is plotted in Figure 12. The magnitude scaling factor for cyclic softening of clay-like soils is discussed in Section 3.3.2.

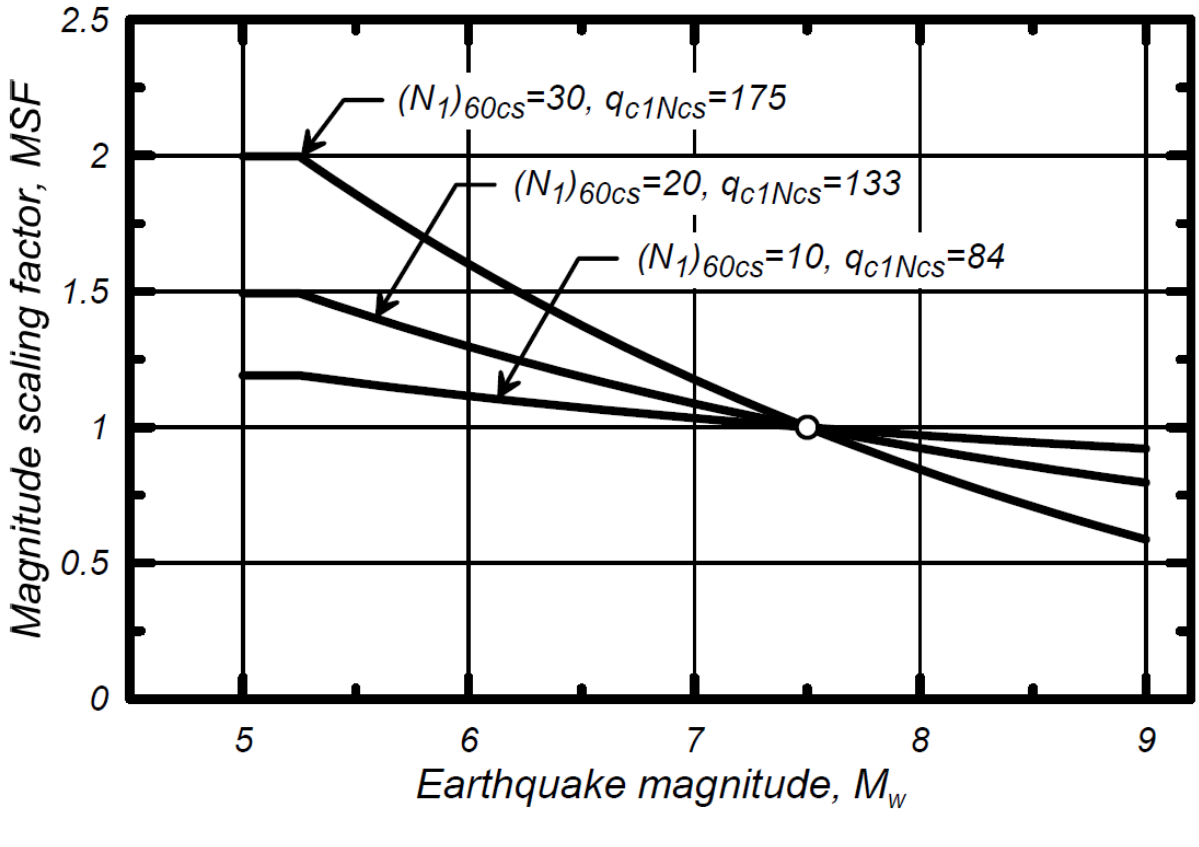

Figure 12. MSF relationship for sand-like soils (Boulanger and Idriss 2014).

3.2.9. CRR Correction for Overburden Stress in Sand-Like Soils

The simplified stress-based approach was originally developed using data from sites with a level to gently sloping surface and soil depths less than about 45 feet (Seed and Idriss 1971). Using laboratory test data,

Seed (1983) proposed two corrections to adjust the CRR for high static overburden stress and static shear stress imposed by a sloping ground surface. The K_σ correction factor extends the simplified procedure to higher overburden stresses and the K_α correction factor permits the consideration of more steeply sloping ground conditions. Both factors, when used to compute CRR per Section 3.2.3, can be significant when considering the liquefaction resistance of soils beneath large embankment dams. The K_σ factor is discussed here, while K_α is discussed separately in Section 3.2.10.

Laboratory data show a nonlinear increase in liquefaction resistance with an increase in effective confining pressure. The K_σ correction factor is thus a function of vertical effective stress, as well as relative density. The K_σ curves in Figure 13 were developed by Boulanger and Idriss (2014), and apply to both SPT and CPT-based analyses. The overburden correction factors in Figure 13 can be expressed as:

Equation 34

$$K_\sigma = 1 - C_\sigma \cdot \ln\left(\frac{\sigma'_v}{P_a}\right) \leq 1.1$$

$$C_\sigma = \frac{1}{18.9 - 2.55 \cdot \sqrt{(N_1)_{60CS}}} \leq 0.3$$

$$C_\sigma = \frac{1}{37.3 - 8.27 \cdot (q_{c1Ncs})^{0.264}} \leq 0.3$$

where P_a is one atmosphere of pressure in the units of the vertical effective stress, σ'_v. C_σ is a coefficient that is a function of relative density (D_R), which Boulanger and Idriss (2014) correlated to SPT blowcount or CPT tip resistance as shown above.

Note that labels on plots should read "$(N_1)_{60CS}$" and "q_{c1Ncs}" instead of "$(N_1)_{60}$" and "q_{c1N}".

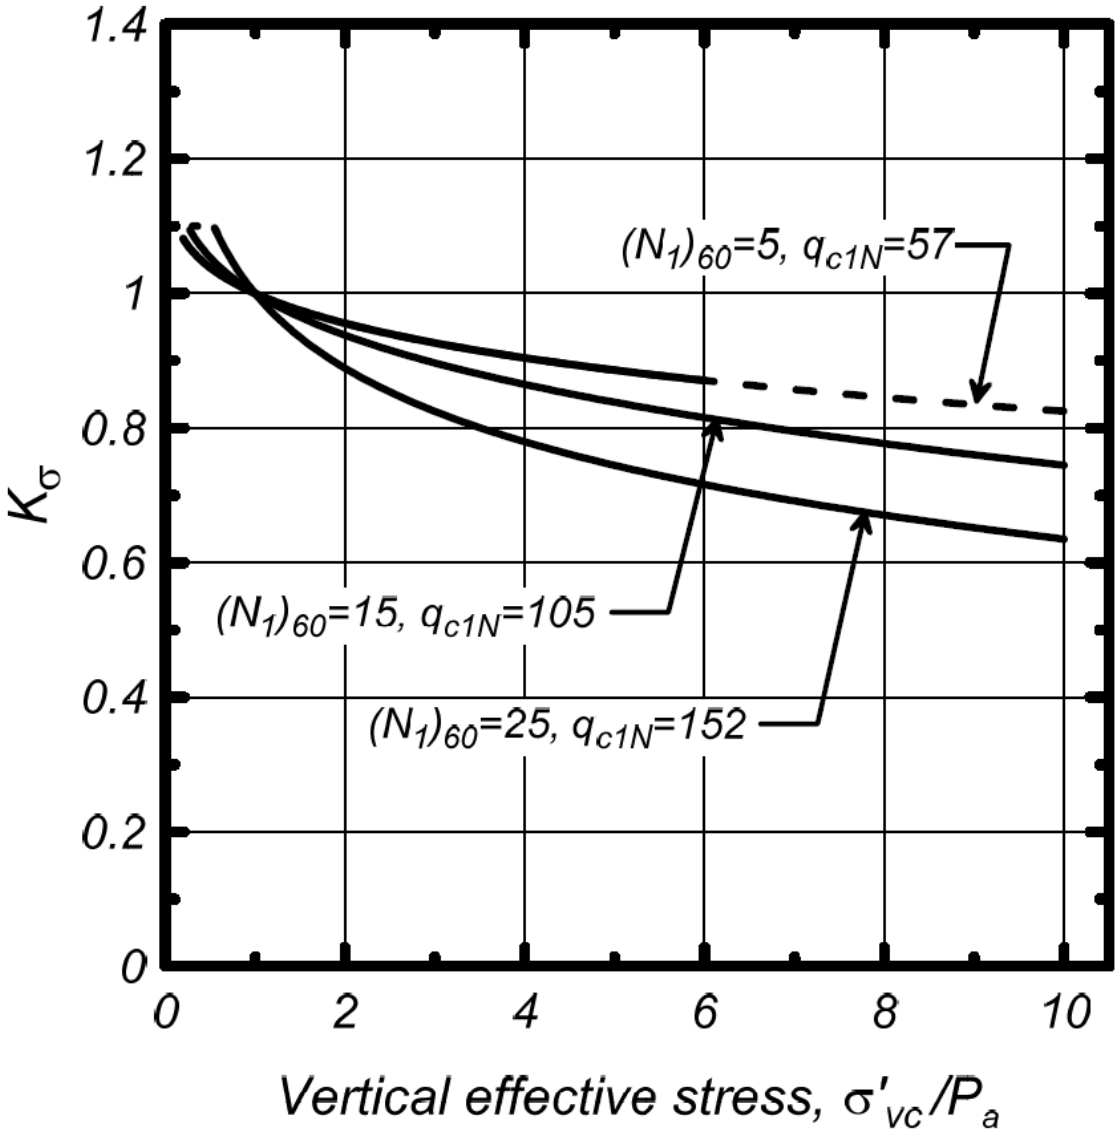

Figure 13. CRR Correction Factor for Overburden Stress (Boulanger and Idriss 2014).

3.2.10. CRR Correction for Static Shear Stress in Sand-Like Soils

A sloping ground surface creates static driving shear stresses in the underlying soil. The magnitude of these stresses is represented by the static shear stress ratio (α), which is defined as:

$$\alpha = \frac{\tau_h}{\sigma'_{vo}} \qquad \textbf{Equation 35}$$

where τ_h is the static shear stress on a horizontal plane, and σ'_{vo} is the vertical effective stress on that plane. The value of α will vary throughout the cross section of an embankment and its foundation. The value depends, in part, on the steepness of the surface slope.

To quantify α, an elastic finite element model is used to estimate and map the distribution of stresses in the cross section. Linear elasticity (with no plastic yielding) is assumed for all material zones in this model. For the initial in-situ stress state, the computed stresses are not sensitive to soil modulus, and a Young's modulus of 1×10^6 psf is assigned to all materials. Poisson's ratios (ν) for each material are approximated using the at-rest lateral earth pressure coefficient (K_o), and the correlation with drained friction angle (ϕ') suggested by Jaky (1944):

$$\nu = \frac{K_o}{1 + K_o} \approx \frac{1 - sin\phi'}{2 - sin\phi'} \qquad \textbf{Equation 36}$$

The elastic stress calculations are completed using the SIGMA/W finite element module in the GeoStudio analysis software package. This analysis is used only to obtain contours of the static stresses; the predicted displacements are of no interest and are ignored. Using the post-processing features in SIGMA/W, vertical profiles of the computed stresses are extracted from the finite element output at the location of an SPT boring or CPT sounding. The shear stress ratio (α) at each depth interval is computed from the shear and normal stresses. Interpolation or a polynomial curve is then used to obtain an estimate of α at the elevation of each SPT blowcount or CPT tip resistance.

The K_α parameter, which is used to modify the CRR (Section 3.2.3) for the effects of static shear stress, can vary widely depending upon the value of α and the relative density of the soil. Static shear stress increases the cyclic resistance of a dense soil under low confining pressure, because higher induced shear stresses are required to cause stress reversal. However, loose soils and some soils under high confining pressures have lower cyclic resistance due to strain softening behavior.

Idriss and Boulanger (2008) present K_α as a function of α and a relative state parameter index (ξ_R), which is the difference between the actual relative density (D_R) and an empirical critical state relative density ($D_{R,CS}$). The critical state relative density is a function of grain type (as it relates to particle crushing) and mean effective stress. For a given α, the value of K_α is computed from these equations (Idriss and Boulanger 2008):

$$K_\alpha = a + b \exp\left(\frac{-\xi_R}{c}\right)$$ **Equation 37**

$$a = 1267 + 636\,\alpha^2 - 634\exp(\alpha) - 632\exp(-\alpha)$$

$$b = \exp[-1.11 + 12.3\,\alpha^2 + 1.31\ln(\alpha + 0.0001)]$$

$$c = 0.138 + 0.126\,\alpha + 2.52\,\alpha^3$$

$$\xi_R = D_{R,CS} - D_R$$ **Equation 38**

$$D_{R,CS} = \frac{1}{Q - \ln\left[\frac{100\,(1 + 2K_o)\,\sigma'_{vo}}{3\,P_a}\right]}$$ **Equation 39**

$$D_R = \sqrt{\frac{(N_1)_{60CS}}{C_d}}$$ **Equation 40**

$$D_R = 0.465\left(\frac{q_{c1Ncs}}{C_{dq}}\right)^{0.264} - 1.063$$

where Q is a function of grain type (assumed to be 10, corresponding to quartz sand), at-rest lateral earth pressure coefficient K_o is assumed to be 0.5, C_d = 46 and C_{dq} = 0.9 (Idriss and Boulanger 2008). Note that the relative density correlations are a function of clean-sand equivalent blow count and tip resistance to be consistent with updated methodology (Boulanger and Idriss 2014). Equation 37 is based on data shown in Figure 14 and thus should be constrained within the following limits: $\alpha \leq 0.35$ and $-0.6 \leq \xi_R \leq 0.1$. Example values of K_α computed in this manner (for Q = 10, K_o = 0.45, and σ'_{vo} = 1 and 4 atm) are presented in the lower plots in Figure 14.

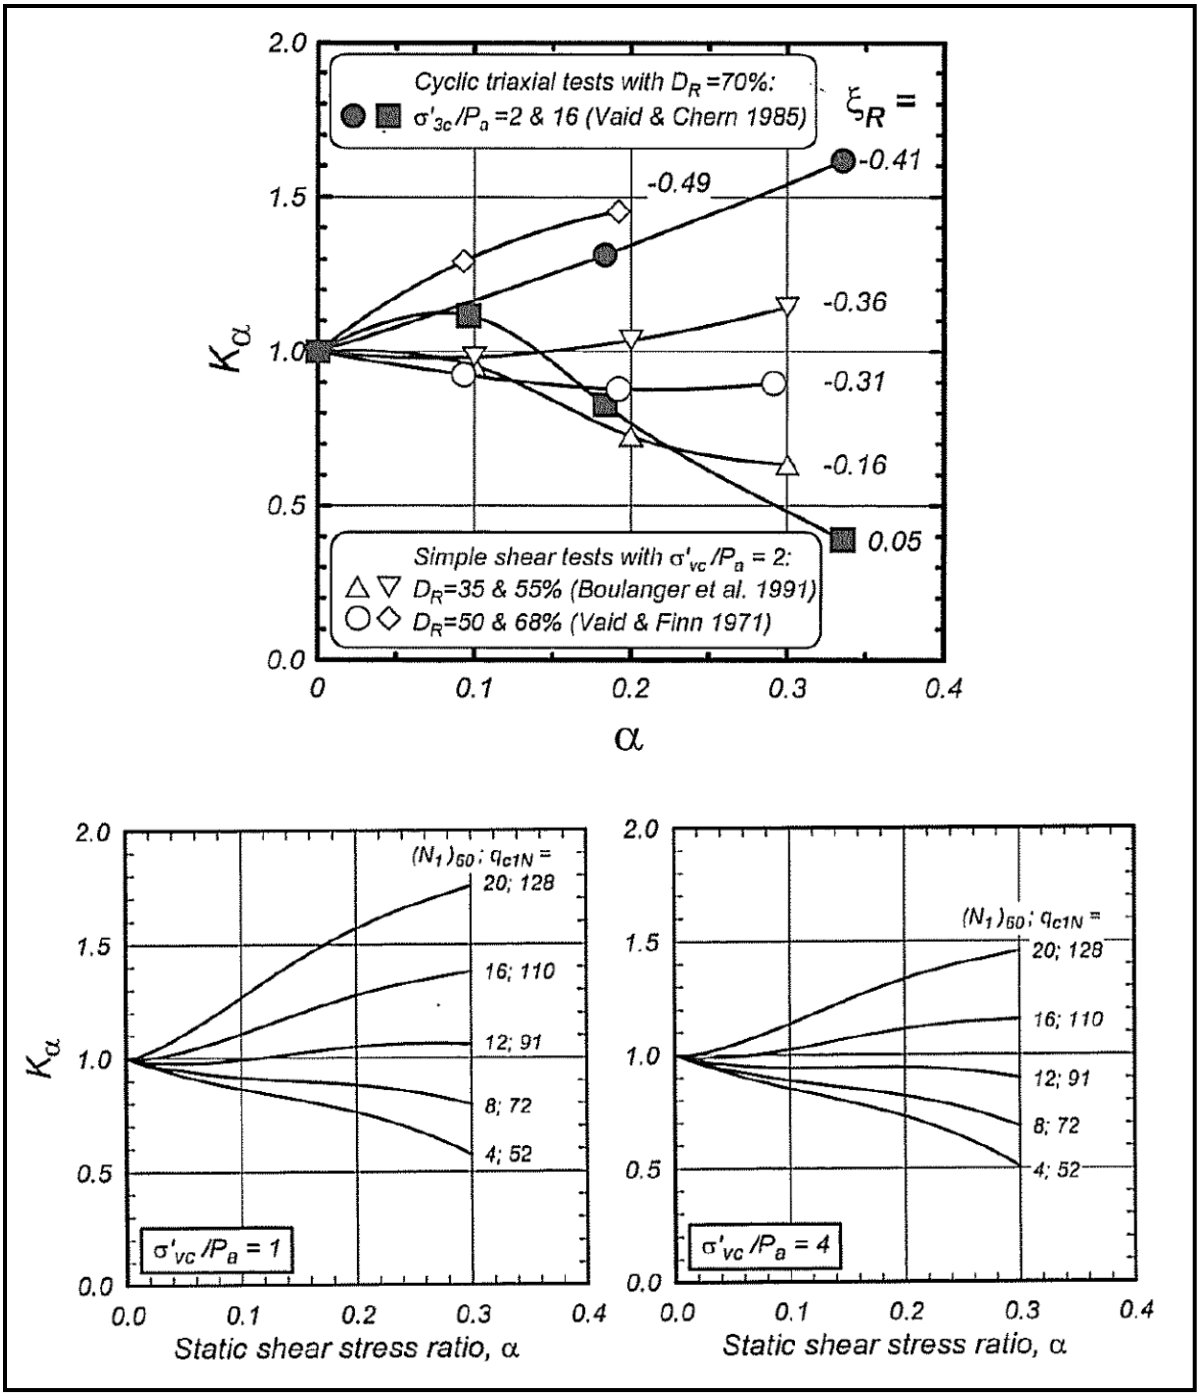

Figure 14. CRR Correction Factor for Static Driving Shear Stress (from Idriss and Boulanger 2008).

3.2.11. Liquefaction Resistance based on Shear Wave Velocity

Empirical correlations with in situ shear wave velocity V_S (Andrus and Stokoe 2000; Youd et al. 2001; Kayen et al. 2013) may be used to quantify liquefaction resistance. These methods are typically used to supplement evaluations based on penetration resistance, or where SPT or CPT data are considered unreliable (for example, in gravelly soil deposits). These approaches may also provide insight into the effects of soil cementation and aging on liquefaction potential, because the materials are not disturbed during testing as with SPT and CPT methods.

The use of V_S to estimate CRR involves several sources of uncertainty. Prior to the work by Kayen et al. (2013), a relatively small database of field case histories was available to develop these methods. The approach requires extrapolating the soil behavior measured under very small cyclic shear strains to predict behavior under much larger strains where pore pressure generation would occur. Finally, in the current relationships, the predicted CRR is sensitive to relatively small changes in V_S. In light of these uncertainties, Idriss and Boulanger (2008) recommend that greater weight be given to results of SPT and/or CPT-based liquefaction triggering analyses.

Shear wave velocities were not used to assess liquefaction in this study.

3.3. CYCLIC SOFTENING OF CLAY-LIKE SOILS

3.3.1. Screening for Susceptibility to Cyclic Softening

For soils identified as having clay-like behavior (Section 3.1.2), additional criteria should be considered to determine if significant strength loss is likely due to cyclic loading. Note that the evaluation for cyclic softening in clay-like soils is often completed for the whole layer or deposit, and not for individual data points of penetration resistance as done for sandy soils.

Three publications provide screening criteria as follows:

(1) Seed et al. (2003), in reference to Figure 4, suggest that fine-grained soils that fall in Zone B and meet the water content requirement may be susceptible to cyclic softening. Soils that fall in Zone C are clay-like, but generally not subject to cyclic softening.

(2) Bray and Sancio (2006) offer a screening method based on plasticity index (PI) and the ratio of the natural moisture content (w_c) to the liquid limit (LL), as shown in Figure 15:

- Susceptible to cyclic softening: PI ≤ 12 and $w_c \geq 0.85$ LL
- Not susceptible: PI > 18 or $w_c < 0.8$ LL
- Moderately susceptible: Intermediate conditions

(3) The MSHA design guidance (D'Appolonia 2010) presents these screening criteria for clay-like soils:

- Susceptible to cyclic softening: SPT $N_{60} < 6$, where the SPT blowcounts are corrected for hammer energy and other test details (Section 3.2.4.1), but not corrected for overburden pressure.
- Susceptible to cyclic softening: CPT results plotting in Zone C of Figure 16.

- Not susceptible: CPT results plotting in Zone B of Figure 16 (note that Zones A_1 and A_2 are sand-like soils).

For clay-like soils, the three sets of screening criteria presented above may provide conflicting indications of behavior under dynamic load. All of these criteria are used together, with engineering judgment, to determine if a particular soil stratum is susceptible to cyclic softening.

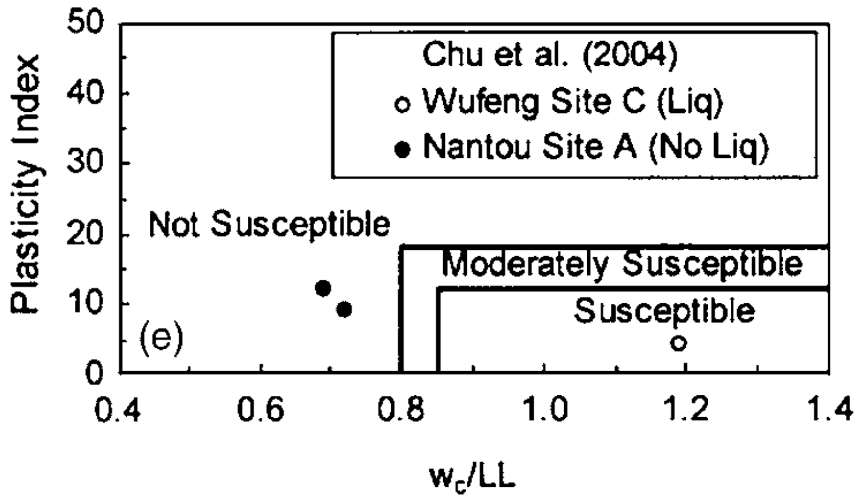

Figure 15. Screening Criteria for Assessing Cyclic Softening in Clay-like Soils (Bray and Sancio 2006).

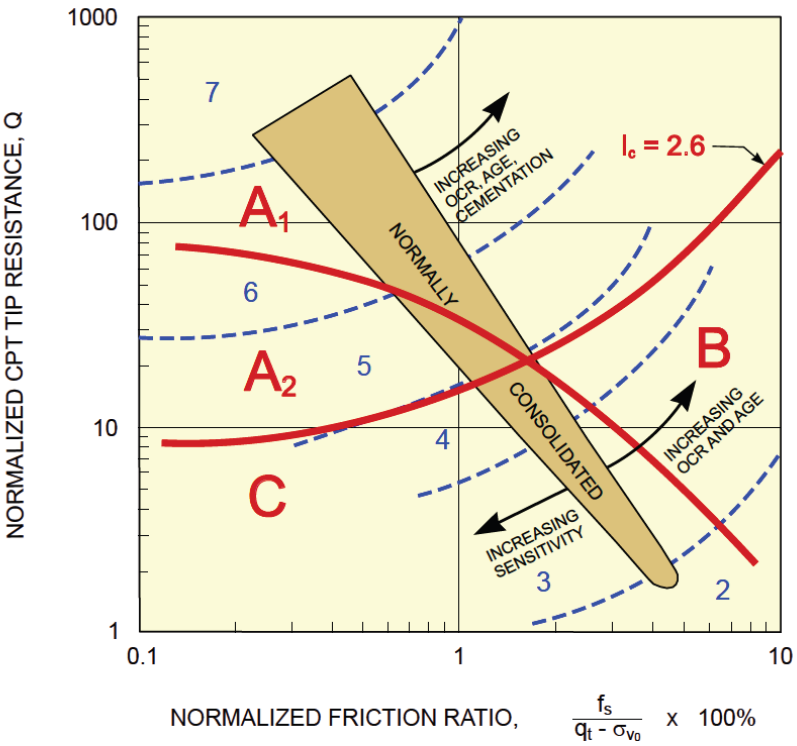

NOTE:
1. VALUES OF Q AND F ARE COMPUTED FROM CPT DATA AT THE DEPTHS OF INTEREST, AS DESCRIBED IN YOUD ET AL. (2001).
2. CPT DATA THAT PLOT IN ZONES A_1 AND A_2 INDICATE MATERIAL THAT IS NOT CONSIDERED CLAY-LIKE, SO THIS SCREENING METHOD IS NOT APPLICABLE.
3. CPT DATA THAT PLOT IN ZONE B INDICATE CLAY-LIKE MATERIAL THAT IS NOT SUSCEPTIBLE TO STRENGTH LOSS.
4. CPT DATA THAT PLOT IN ZONE C INDICATE CLAY-LIKE MATERIAL THAT MAY BE SUSCEPTIBLE TO STRENGTH LOSS.
5. NUMBERED ZONES SEPARATED BY DASHED BLUE LINES ARE FOR REFERENCE ONLY AND ARE A GUIDE TO SOIL TYPES, AS DESCRIBED IN YOUD ET AL. (2001). FOR EXAMPLE, DATA IN ZONE 3 INDICATE SILTY CLAY TO CLAY WHILE DATA IN ZONE 6 INDICATE CLEAN SAND TO SILTY SAND. THE LINE SEPARATING SAND-LIKE FROM CLAY-LIKE MATERIAL CORRESPONDS TO A SOIL BEHAVIOR TYPE INDEX (I_c) OF 2.6, AS ALSO DESCRIBED IN YOUD ET AL. (2001).

Figure 16. Screening Criteria for Assessing Cyclic Softening in Clay-like Soils (D'Appolonia 2010; adapted from Robertson 2008).

3.3.2. Factor of Safety for Cyclic Softening

If a clay-like soil is screened as susceptible to cyclic softening, further analysis is performed to evaluate the potential for triggering in a given earthquake. Using the empirical method developed by Idriss and Boulanger (2008), the cyclic resistance of a clay-like soil is estimated based on the static undrained strength ratio. The evaluation is made using a strength ratio that is representative of the entire soil layer, instead of using SPT or CPT data for certain depth increments. Key aspects of this method are summarized below.

The factor of safety for triggering cyclic softening in clay-like soils is analogous to the factor of safety for liquefaction in sand-like soils (Equation 13). For characterizing clay-like soils, failure due to cyclic softening is assumed to occur at 3% cyclic shear strain (γ = 3%). The factor of safety for cyclic softening of clay-like soils is then defined as:

$$\left(FS_{\gamma=3\%}\right)_{clay} = \frac{(CRR)_{clay}}{CSR} \qquad \textbf{Equation 41}$$

The CSR is the cyclic stress ratio (Section 3.2.2). The CSR for evaluating cyclic softening in clay-like soils is the same as used to evaluate liquefaction in sand-like soils (see Equation 15).

3.3.3. Cyclic Resistance Ratio for Clay-Like Soils

The cyclic resistance ratio (CRR) for a reference earthquake of M = 7.5 is 80% of the "c/p ratio" for the clay-like soil (see Exhibit J.4). That is:

$$(CRR_{7.5})_{clay} = 0.80 \cdot \frac{S_u}{\sigma'_{vo}} \qquad \textbf{Equation 42}$$

S_u is the static undrained shear strength and σ'_{vo} is the vertical effective stress during consolidation.

The reference CRR is modified for earthquake magnitude and initial static shear stress:

$$(CRR)_{clay} = (CRR_{7.5})_{clay} \cdot MSF_{clay} \cdot (K_\alpha)_{clay} \qquad \textbf{Equation 43}$$

3.3.4. Magnitude Scaling Factor for Clay-Like Soils

Cyclic laboratory testing on clay-like soils has shown that the typical relationships between CSR and number of uniform cycles to failure are much flatter than for sands. Thus, the relationship between MSF and earthquake moment magnitude (M) is also much flatter, as shown in Figure 17 (Idriss and Boulanger 2008):

$$MSF_{clay} = 1.12 \cdot \exp(-0.25M) + 0.828 \leq 1.13 \qquad \textbf{Equation 44}$$

3.3.5. CRR Correction for Static Shear Stress in Clay-Like Soils

The effects of initial static shear stress on the cyclic strength of clay can be expressed using a K_α factor, as with sands. The correction factor for clays is (Idriss and Boulanger 2008):

$$(K_\alpha)_{clay} = 1.344 - \frac{0.344}{\left(1 - \frac{\alpha}{0.22 \cdot (OCR^{0.8})}\right)^{0.638}} \qquad \textbf{Equation 45}$$

The static driving shear stress is represented by the shear stress ratio, α (Equation 35), and OCR is the overconsolidation ratio.

Note that MSF equation for sand shown in this figure has been superseded. See Figure 12.

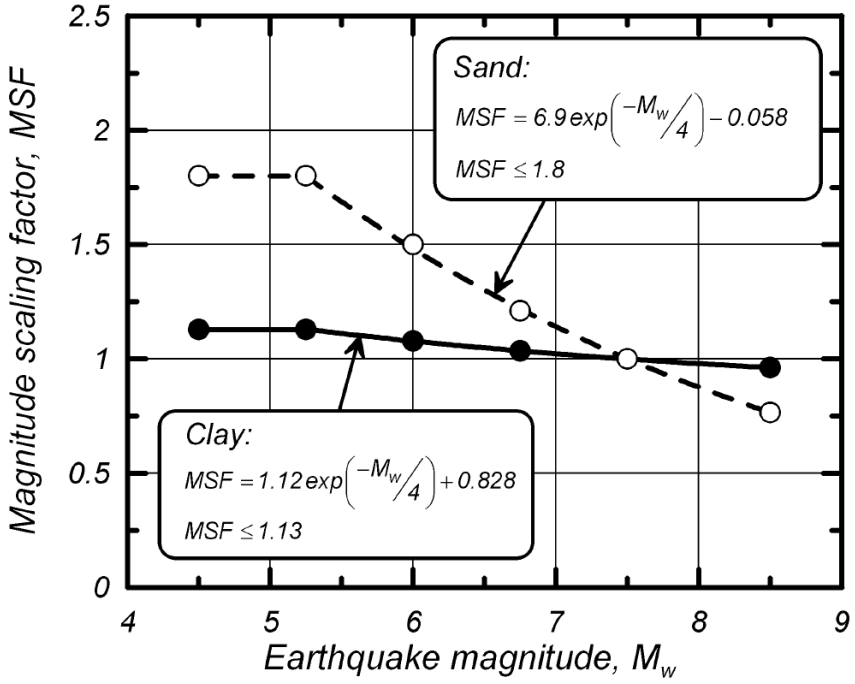

Figure 17. MSF relationship for clay-like soils (Idriss and Boulanger 2008).

4. SEISMIC DEFORMATION ANALYSIS

4.1. CONDITIONS REQUIRING DEFORMATION ANALYSIS

An earthquake may cause excessive embankment deformations, even if the slopes are otherwise stable. Embankment displacements resulting from an earthquake are predicted if both of the following conditions are met:

- Soil liquefaction is not predicted,
- The post-earthquake static stability analysis indicates a factor of safety greater than or equal to 1.0.

In this case, the seismic deformations are estimated using Newmark displacement analyses, as described in Section 4.2.

More advanced methods (Section 4.3) are required to estimate seismic deformations if the slopes are not seismically stable. The embankment slopes should be treated as unstable if significant liquefaction occurs and the post-earthquake factor of safety is less than 1.0.

Note that SRME-SPP-27.001 requires deformation analyses when the post-earthquake factor of safety is greater than or equal to 1.1. However, in accordance with TVA's scope of work for this project, deformation analyses are required when the post-earthquake factor of safety is greater than or equal to 1.0.

4.2. DEFORMATION OF STABLE SLOPES

4.2.1. Newmark Analyses

If an earth slope is seismically stable, the magnitude of earthquake-induced permanent deformations can be estimated using a Newmark sliding block analysis (Newmark 1965). The Newmark displacement analysis is based on the analogy of a block sliding down an inclined plane. When the plane is shaken, the block accelerates down the plane whenever the static and dynamic sliding forces exceed the sliding resistance. Movement of the block slows (de-accelerates) when the sliding resistance is greater than the sliding forces. The block thus moves down the plane in pulses, and the accumulated displacements can be computed by double integration of the input acceleration record (Figure 18).

In a slope stability problem, this analogy translates to the failure mass sliding whenever the horizontal, downslope ground acceleration exceeds the horizontal yield acceleration for the failure surface. The failure surface geometry and associated yield acceleration for a soil mass are found from pseudostatic, limit equilibrium, slope stability analyses. The input ground motion is estimated by performing ground response analyses at multiple locations along the failure surface and averaging these motions. Finally, the acceleration time history of the input motion is compared to the yield acceleration. Where the input, downslope acceleration exceeds the yield acceleration, the time history is integrated twice to calculate displacements (Figure 18). Displacements accumulate over the time history to produce an estimate of the total permanent deformation due to the earthquake. Slope displacements are assumed to stop when the earthquake ends, consistent with the assumption of post-earthquake stability.

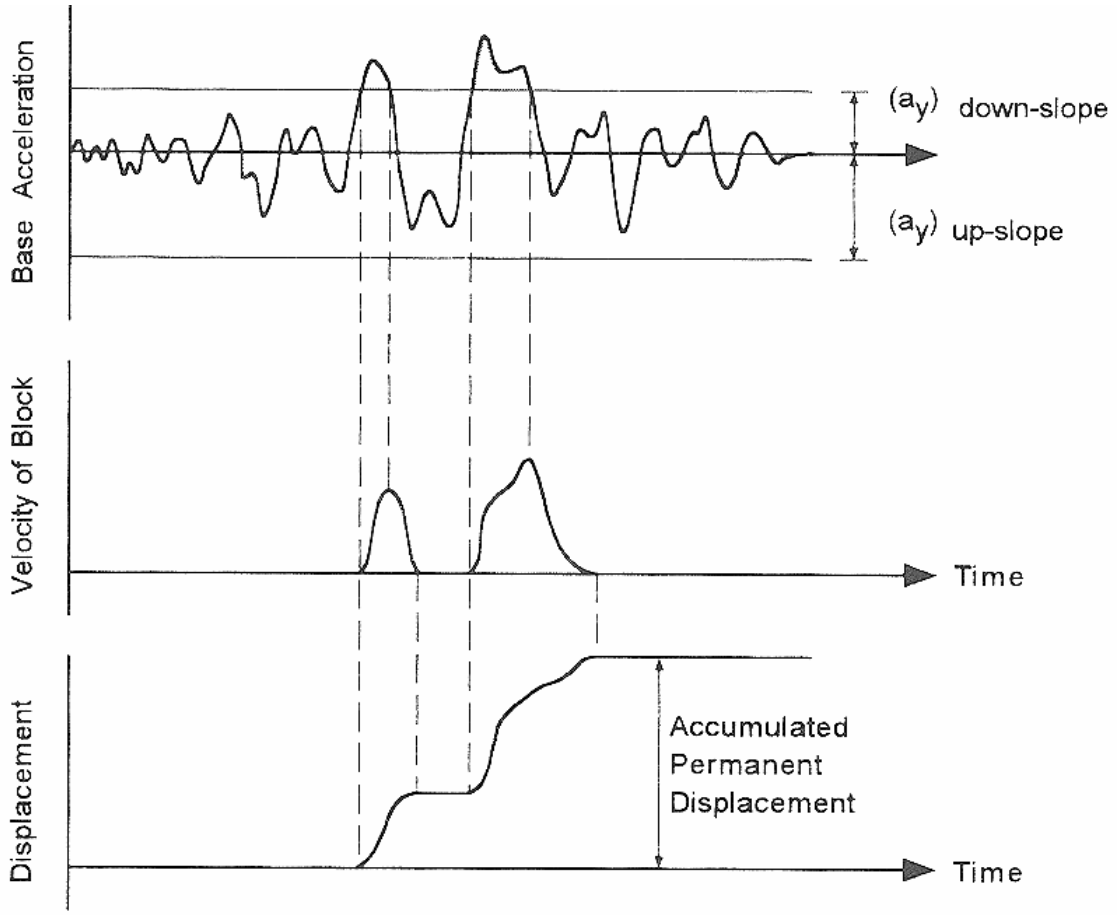

Figure 18. Calculation of Permanent Displacement in a Newmark Type Analysis (after Kramer 1996).

The yield acceleration (k_y) for a given slope is determined from a series of pseudostatic slope stability analyses, in which the horizontal pseudostatic coefficient (k_h) is varied in each trial. For each trial k_h, the critical slip surface is located and the factor of safety (FS_{slope}) is computed in a two-stage, limit equilibrium analysis. The yield acceleration (k_y), expressed as a fraction of the acceleration due to gravity, is equal to the value of k_h that results in FS_{slope} equal to one.

Where the surficial embankment materials are cohesionless, an infinite slope mechanism (with a shallow slip surface) will be critical. However, shallow sloughing could be repaired after an earthquake. This seismic assessment is focused on mechanisms that might result in an unacceptable condition; hence, the deformation analyses consider only slip surfaces that are deep enough to intercept the CCR stored within the unit. This treatment is consistent with the evaluations of static slope stability.

Assuming no liquefaction, the predicted slope displacements are somewhat conservative because the yield acceleration is computed with reduced, undrained soil strengths. In reality, the yield acceleration declines in successive cycles of seismic loading, as pore pressures accumulate and saturated soils become weaker. The analysis outlined here assumes reduced strengths at the start of the earthquake, so the computed yield acceleration is lower than the initial value in the slope.

4.2.2. Equivalent Acceleration Time History

A conventional Newmark displacement analysis assumes that the soil above the failure surface behaves as a rigid mass, when the soil mass is actually flexible. As a result, different ground motion time histories occur at different elevations, and those motions are out of phase. The flexibility of the soil profile above the failure plane can be modeled using equivalent-linear ground response analyses, and partly accounted for in a Newmark analysis by using a "horizontal equivalent acceleration" (HEA). The HEA is the acceleration in a flexible soil profile that would cause the same time history of shear stress if the materials above the failure plane were rigid. Equation 46, derived using Newton's second law for the horizontal acceleration of a rigid block (Kramer and Smith 1997), expresses the HEA time history as a function of the shear stress time history on a failure surface.

$$HEA(t) = \frac{\tau_h(t)}{\sigma_v} \cdot g \qquad \textbf{Equation 46}$$

Here, $\tau_h(t)$ is the time history of shear stress on the failure surface, σ_v is the total vertical stress at the failure surface, and g is the acceleration due to gravity. When computed at different points along a failure surface, the HEA will vary with position. Abramson et al. (2002) suggest computing HEA at different offsets and computing a weighted average:

$$HEA_{avg}(t) = \frac{\sum_{i=1}^{i=n} m_i \cdot HEA_i(t)}{\sum_{i=1}^{i=n} m_i} = \frac{\sum_{i=1}^{i=n} \sigma_{vi} \cdot HEA_i(t)}{\sum_{i=1}^{i=n} \sigma_{vi}} \qquad \textbf{Equation 47}$$

Here, m_i is the mass of the overlying column above point i, σ_{vi} is total vertical stress at point i, and $HEA_i(t)$ is the horizontal equivalent acceleration time history at point i. If we consider three different points (A, B, and C) along the failure surface, and substitute Equation 46 for $HEA_i(t)$ in Equation 47, the relationship simplifies to:

$$HEA_{avg}(t) = \frac{\tau_{hA}(t) + \tau_{hB}(t) + \tau_{hC}(t)}{\sigma_{VA} + \sigma_{VB} + \sigma_{VC}} \cdot g \qquad \textbf{Equation 48}$$

For estimating the displacement on a slope, $HEA_{avg}(t)$ is computed using ground response analyses for vertical soil profiles at the crest, mid-height, and toe of the slope (locations A, B, and C in Equation 48). That is, three separate ground response analyses (Section 2) are completed for soil profiles at the crest, mid-height, and toe of the slope. Where the slip surface (corresponding to the yield acceleration) does not extend to the crest or toe, the profiles may be moved to locations near the top, middle, and bottom of the slide mass. More than three profile locations may be needed to adequately represent large slide masses or complex failure mechanisms. For each ground response analysis, the shear stress time histories and total vertical stresses ($\tau_h(t)$ and σ_v) are recorded at the elevation of the slip surface for the yield acceleration. The results are then combined to compute the average HEA time history, per Equation 48.

The resulting average HEA time history is then compared to the yield acceleration, and any periods of exceedance are double integrated to calculate permanent displacements along the critical slip surface. The computation of the HEA time history and the double integration is completed in a spreadsheet calculation.

4.2.3. Summary of Procedure

Displacements are computed and reported for each cross section, for upstream and downstream slope movements, and for each earthquake time history. To summarize, the displacement calculation for each case involves the following steps:

(1) Run a series of pseudostatic slope stability analyses, varying the horizontal pseudostatic coefficient (k_h) and searching for the critical slip surface in each run. Ignore shallow slip surfaces that do not encompass the full width of the dam crest.

(2) The value of k_h that results in $FS_{slope} = 1.0$ is the yield acceleration (k_y); record the yield acceleration and the geometry of the associated slip surface.

(3) Select three (possibly more) offset locations for computing acceleration time histories, usually at the crest/mid-slope/toe of the slope, or the top/middle/bottom of the slide mass.

(4) Run a ground response analysis (Section 2) for each of the selected profiles, recording the time history of shear stresses at the elevation where the slip surface crosses the profile.

(5) Compute the average time history, $HEA_{avg}(t)$ per Equation 48, using the shear stress time histories and vertical stresses on the slip surface at the selected offset locations.

(6) Compute the predicted displacement using the average HEA time history and the yield acceleration.

4.3. DEFORMATION OF UNSTABLE SLOPES

Earth slopes should be considered seismically unstable if significant liquefaction occurs and the post-earthquake factor of safety for slope stability is less than the limit stated in Section 4.1. In this case, large deformations and a slope failure should be expected. If the factor of safety is low enough, slope movements may continue after the seismic ground motions stop. The methods described in Section 4.2 are inadequate for modeling this case, and more advanced methods of analysis are required.

If significant soil liquefaction is triggered by an earthquake, the acceleration time histories at points above the liquefied zone, as predicted by the ground response analysis, will be unreliable. Hence, the methods described in Section 4.2 are not suitable if liquefaction occurs.

1.0 INTRODUCTION

Stantec Consulting Services Inc. (Stantec) has prepared this Sampling and Analysis Report (SAR) on behalf of the Tennessee Valley Authority (TVA) to document the activities related to a coal combustion residuals (CCR) material characteristics investigation at TVA's Kingston Fossil (KIF) Plant located at 714 Swan Pond Road in Harriman, Tennessee.

The purpose of the CCR material characteristics investigation is to characterize leachability of CCR-related constituents from material within two CCR units at the KIF Plant, in support of fulfilling the requirements for the Tennessee Department of Environment and Conservation (TDEC) issued Commissioner's Order No. OGC15-0177 (TDEC Order) to TVA (TDEC 2015). The TDEC Order sets forth a "process for the investigation, assessment, and remediation of unacceptable risks" at the TVA's coal ash disposal sites in Tennessee.

The purpose of this SAR is to document the work completed during the CCR material characteristics investigation and to present the information and data collected during the execution of the CCR Material Characteristics Sampling and Analysis Plan (SAP) (Stantec 2018a). This SAR is not intended to provide conclusions or evaluations of results. The scope of the CCR material characteristics investigation represented herein was conducted pursuant to the SAP and is part of a larger environmental investigation at the KIF Plant. The evaluation of the results will consider other aspects of the environmental investigation, as well as data collected under other State and/or CCR programs, and be presented in the Environmental Assessment Report (EAR).

The CCR material characteristics investigation activities were performed in conjunction with the exploratory drilling investigation at the KIF Plant in general accordance with the following documents developed by TVA to support fulfilling the requirements of the TDEC Order:

- *CCR Material Characteristics SAP* (Stantec 2018a)
- *Environmental Investigation Plan (EIP)* (Stantec 2018b)
- *Exploratory Drilling SAP* (Stantec 2018c*)*
- *Quality Assurance Project Plan (QAPP)* (Environmental Standards, Inc. 2018).

The CCR Material Characteristics SAP was implemented in accordance with TVA- and TDEC- approved Programmatic- and Project-specific changes. Minor variations in scope and procedures from those outlined in the CCR Material Characteristics SAP occurred during field activities due to field conditions and programmatic updates and are referenced in Section 3.6.

Laboratory analysis of constituents was performed by TestAmerica Laboratories, Inc. (TestAmerica) in St. Louis, Missouri (radium samples only), and in Pittsburgh, Pennsylvania (all other analytes). Additional Quality Assurance oversight on data acquisition protocols, sampling practices, and data validation and/or verification was performed by Environmental Standards, Inc. (EnvStds) under direct contract to TVA.

2.0 OBJECTIVE AND SCOPE

The primary objective of the CCR material characteristics investigation conducted pursuant to the CCR Material Characteristics SAP at the KIF Plant was to collect CCR material and pore water samples for characterization related to the leachability of CCR-related constituents from material within two CCR units: the Interim Ash Staging Area and the Sluice Trench and Ballfield East of Sluice Trench. The approach for the investigation was to:

- Collect CCR material samples for chemical analyses from the temporary well borings and other borings drilled as part of the KIF Plant exploratory drilling investigation
- Following installation and development of the temporary wells, measure pore water levels and collect pore water samples for chemical analyses.

The scope of work of the CCR material characteristics investigation consisted of the following tasks:

- Collecting CCR material samples and associated quality control (QC) samples at the temporary well borings for laboratory analysis of CCR-related constituents and to identify the interface between the CCR material and underlying foundation soils during drilling
- Collecting pore water level measurements
- Collecting pore water samples and associated QC samples from the temporary wells for analysis of CCR-related constituents and water quality parameters.

These activities were carried out concurrently with advancement of borings and after the installation of temporary wells conducted as part of the KIF Plant exploratory drilling investigation. Drilling, geotechnical sampling, and temporary well installation and development activities were performed in accordance with the Exploratory Drilling SAP and reported in the KIF Plant Exploratory Drilling SAR.

3.0 FIELD ACTIVITIES

CCR material characteristics investigation field activities were conducted between November 12, 2018 and April 12, 2019, and between December 2 and 5, 2019. Stantec performed field activities for the CCR material characteristics investigation based on guidance and specifications listed in TVA's Environmental (ENV) Technical Instructions (TIs), the SAP, and the QAPP, except as noted in the Variations section of this report. As part of TVA's commitment to generate representative and reliable data, data validation and/or verification of laboratory analytical data was performed by EnvStds under direct contract with TVA. EnvStds also conducted audits of field activities and provided quality reviews of field documentation. In addition, on behalf of TDEC, Civil and Environmental Consultants, Inc. (CEC) collected split CCR material samples during this sampling event. Additional information regarding CEC split sample collection is provided in Sections 3.3.2 and 3.3.3.2.

During the CCR material characteristics investigation, Stantec conducted the following field activities:

- Collected CCR material samples at the five temporary well borings and seven additional borings during drilling
- Recorded field measurements of CCR material pH at the 12 sampled boring locations (see Section 3.3.2 for more detail)
- Following temporary well installation and development activities, collected pore water level measurements from the five temporary wells prior to sampling
- Recorded field measurements of pore water quality parameters during purging and stabilization at the five sampled temporary wells
- Collected filtered and unfiltered pore water samples from the five temporary well locations
- Collected QC samples including four matrix spike/matrix spike duplicates, five field duplicates, 18 field blanks, four equipment blanks, one liner blank, one tubing blank, and one filter blank
- Conveyed collected samples via a laboratory-provided courier service to TestAmerica for analysis.

Details on each activity are presented in the sections below. The CCR material characteristics investigation temporary wells and additional boring locations are shown on Exhibit A.1 in Appendix A. Appendix B provides tabulated information collected during the investigation, including summaries of samples collected, pore water measurements, field measurements, and analytical results in Tables B.1 through B.9. Subsurface boring logs and photographic logs of the CCR material cores are provided in Appendices C and D, respectively.

3.1 WORK LOCATIONS

The CCR material characteristics investigation field activities were initially completed at five temporary well locations (KIF-TW01 through KIF-TW05) at the KIF Plant under the CCR material characteristics investigation scope of work. Following analysis of the CCR material samples from the five temporary wells, seven additional borings (KIF-B01a, KIF-B01b, KIF-B02a, KIF-B02b, KIF-B03a, KIF-B03b, and KIF-B04a) were advanced and sampled to fulfill the scope for both the exploratory drilling and CCR material characteristics investigations. The objective of the additional borings was to drill and sample the uppermost foundation soils underlying the two CCR units and identify the CCR material and foundation soil interface. Temporary well and additional boring locations are shown on Exhibit A.1 in Appendix A.

Prior to the successful completion of boring KIF-TW03, two other drilling attempts (KIF-TW03a and KIF-TW03b) were made near the northeast boundary of the Interim Ash Staging Area. During drilling and sampling at boring KIF-TW03a, the hollow stem auger (HSA) drill rig and split spoon sampler were unable to be advanced and the location was moved to boring KIF-TW03b, where the same issue was encountered. Based on review of available information, the locations of borings KIF-TW03a and KIF-TW03b had been advanced in a previously decommissioned area partially filled with rock and gravel. The location was then moved outside of the decommissioned area footprint and boring KIF-TW03 was completed, as shown on Exhibit A.1 in Appendix A. Analytical samples were not submitted for analysis from boring locations KIF-TW03a and KIF-TW03b.

A summary of the boring and temporary well locations is provided in Table 1 below.

Table 1 - Summary of Boring and Temporary Well Locations

Boring ID	Temporary Well ID	Location	Rationale
KIF-TW01	KIF-TW01	Northwest boundary of Interim Ash Staging Area	To assess CCR material characteristics and pore water quality
KIF-TW02	KIF-TW02	Southwest boundary of Interim Ash Staging Area	To assess CCR material characteristics and pore water quality
KIF-TW03	KIF-TW03	Northeast boundary of Interim Ash Staging Area	To assess CCR material characteristics and pore water quality
KIF-TW03a	NA	Attempted near Northeast boundary of Interim Ash Staging Area, within decommissioned area partially filled with rock and gravel	Attempted to assess CCR material characteristics and pore water quality. Hit refusal before reaching planned depth
KIF-TW03b	NA	Attempted near Northeast boundary of Interim Ash Staging Area, within decommissioned area partially filled with rock and gravel	Attempted to assess CCR material characteristics and pore water quality. Hit refusal before reaching planned depth
KIF-TW04	KIF-TW04	Southwest boundary of Sluice Trench and Ballfield East of the Sluice Trench	To assess CCR material characteristics and pore water quality

Table 1 - Summary of Boring and Temporary Well Locations (continued)

Boring ID	Temporary Well ID	Location	Rationale
KIF-TW05	KIF-TW05	Northeast boundary of Sluice Trench and Ballfield East of the Sluice Trench	To assess CCR material characteristics and pore water quality
KIF-B01a	NA	Northwest boundary of Interim Ash Staging Area, within 50 feet of temporary well KIF-TW01	To identify the interface between the CCR material and foundation soil
KIF-B01b	NA	Northwest boundary of Interim Ash Staging Area, within 50 feet of temporary well KIF-TW01	To identify the interface between the CCR material and foundation soil. Second boring was necessary for adequate sample volume
KIF-B02a	NA	Southwest boundary of Interim Ash Staging Area, within 50 feet of temporary well KIF-TW02	To identify the interface between CCR material and foundation soil
KIF-B02b	NA	Southwest boundary of Interim Ash Staging Area, within 50 feet of temporary well KIF-TW02	To identify the interface between CCR material and foundation soil. Second boring was necessary for adequate sample volume
KIF-B03a	NA	Northeast boundary of Interim Ash Staging Area, within 50 feet of temporary well KIF-TW03	To identify the interface between CCR material and foundation soil
KIF-B03b	NA	Northeast boundary of Interim Ash Staging Area, within 50 feet of temporary well KIF-TW03	To identify the interface between CCR material and foundation soil. Second boring was necessary for adequate sample volume
KIF-B04a	NA	Southwest boundary of Sluice Trench and Ballfield East of the Sluice Trench, within 50 feet of temporary well KIF-TW04	To identify the interface between CCR material and foundation soil

Notes:
ID Identification
NA Not Applicable (temporary well not installed)

3.2 DOCUMENTATION

Stantec planned the CCR material characteristics investigation activities per ENV-TI-05.08.01, *Planning Sampling Events* and maintained field documentation in general accordance with ENV-TI-05.80.03, *Field Record Keeping* and the QAPP. Field activities and data were recorded on program-specific field forms. Health and safety forms were completed in accordance with TVA and Stantec health and safety requirements. Additional information regarding each activity is presented in the sections below.

3.2.1 Field Forms

Stantec used program-specific field forms to record field observations and data for specific activities. Field forms used during the CCR material characteristics investigation included:

- *Daily Field Activity Log*
- *Subsurface Log*
- *Soil pH Calibration and Inspection Log*
- *Soil pH Data Form*
- *Monitoring Well Inspection Checklist*
- *Equipment Calibration Form*
- *Water Level Measurement Form*
- *Water Sampling Form*
- *Chain-of-Custody (COC).*

Documentation for the temporary well installation and well development is described in the KIF Plant Exploratory Drilling SAR.

3.2.1.1 Daily Field Activity Log

Stantec field sampling personnel (FSP) recorded daily field activities, observations and data on a *Daily Field Activity Log* to chronologically document the field program. Deviations from the SAP, TIs, or QAPP were documented on the *Daily Field Activity Log*.

3.2.1.2 Subsurface Log

A Professional Geologist (PG) licensed in the State of Tennessee, prepared a *Subsurface Log* for each boring. The log documented time, boring location, drilling personnel, tooling/equipment used, depth to water, sample number, sample recovery, Standard Penetration Test blow counts, subsurface lithology and other relevant observations. CCR material color was logged per the appropriate Munsell Soil Color Chart (Munsell Color 2009). The *Subsurface Logs* are provided in Appendix C.

3.2.1.3 Soil pH Calibration and Inspection Log

Stantec FSP recorded daily soil pH meter calibrations and inspections on a *Soil pH Calibration and Inspection Log*. The log documented temperature, temperature verification, temperature-adjusted calibration values, post calibration pH values, and calibration solution details. Additional information on equipment calibration is provided in Section 3.2.2.

3.2.1.4 Soil pH Data Form

Stantec FSP prepared a *Soil pH Data Form* for each day that pH measurements were taken of the CCR material samples. The form documented the sample identification (ID), boring ID, the depth range, pH measurement date and time, and the field pH value.

3.2.1.5 Monitoring Well Inspection Checklist

Prior to measuring water levels, Stantec FSP inspected each temporary well for damage or indications that the well integrity had been compromised in accordance with ENV-TI-05.80.21, *Monitoring Well Inspection and Maintenance*. Inspection results were documented on a *Monitoring Well Inspection Checklist*. No signs of damage or repairs were noted.

3.2.1.6 Equipment Calibration Form

Stantec FSP performed daily equipment calibrations of the water quality meter and documented the results on an *Equipment Calibration Form*. The form documented the calibration test results for temperature, turbidity, specific conductance, pH, dissolved oxygen (DO), and oxidation-reduction potential (ORP), and verified that the field instruments' sensors were operating within acceptable criteria. Refer to Section 3.2.2 for additional details on equipment calibration procedures.

3.2.1.7 Water Level Measurement Form

Stantec FSP recorded pore water level measurement data on a *Water Level Measurement Form* in accordance with ENV-TI-05.80.44, *Groundwater Level and Well Depth Measurement*. The form includes the temporary well ID, time, and depth to water measured from a standardized reference point on the top of each well casing, recorded in feet below top of casing.

3.2.1.8 Water Sampling Form

Stantec FPS recorded the depth to water, purge flow rate, volume of water purged, temperature, pH, specific conductance, DO, ORP, turbidity, color of water, and other observations during temporary well purging and pore water sampling activities in accordance with ENV-TI-05.80.42, *Groundwater Sampling*. Field measurements were recorded on a *Water Sampling Form*. The form also documents the time intervals between measurement of field parameters, low-flow extraction rates, water level drawdown, and water quality parameter measurements during purging and after stabilization criteria were met.

3.2.1.9 Chain-of-Custody

Stantec FSP completed *COC* documentation for each CCR material and pore water sample collected during the CCR material characteristics investigation. The sample ID, sample location, sample depth (if applicable), type of sample, sampling date and time, analyses requested, and sample custody record were recorded on the *COC*. The Field Team Leader reviewed the *COCs* for completeness and accuracy and the FSP conducted a QC check of samples in each cooler compared to sample IDs on the corresponding *COC* prior to submittal to the laboratory. *COCs* were completed in accordance with ENV-TI-05.80.02*: Sample Labeling and Custody*.

3.2.2 Equipment Calibration

3.2.2.1 CCR Material Equipment Calibration

The pH meter used to collect, generate, or measure environmental data for the CCR material were calibrated each day prior to sampling as specified by the SAP, QAPP, and Stantec Standard Operating Procedure - Rev 1 for the ExTech ExStik 110 meter (Stantec 2018d). Temperature was recorded using a calibrated National Institute of Standards and Technology (NIST) traceable thermometer. Additional details regarding equipment calibration were recorded on the *Soil pH Calibration and Inspection Log*, as described in Section 3.2.1.3.

3.2.2.2 Pore Water Equipment Calibration

Field instruments used to collect, generate, or measure water quality parameters data were calibrated each day prior to sampling as specified by the SAP, QAPP, and ENV-TI-05.80-.46, *Field Measurement Using a Multi-Parameter Sonde*. Afternoon calibration verifications were performed to evaluate if instruments remained within acceptable criteria during sampling. Temperature and barometric pressure were recorded using a calibrated NIST traceable thermometer and the National Weather Service (via mesowest.utah.edu) barometric pressure readings for Oak Ridge National Laboratory (KOQT), Oak Ridge, Tennessee, respectively. Additional details regarding equipment calibration were recorded on the *Equipment Calibration Form*, as described in Section 3.2.1.6.

3.2.3 Photographs

Photographs of the CCR material cores from boring drilling activities were taken during the CCR material characteristics investigation. Photographic logs of CCR material cores from temporary well borings and additional borings are provided in Attachments D.1 and D.2, respectively, in Appendix D.

3.3 SAMPLING METHODS

The following sections present soil sampling procedures used in the CCR material characteristics investigation. Additional information regarding drilling and sampling procedures for temporary well locations is provided in the Exploratory Drilling SAR. Drilling and sampling activities were performed under the direction of a Stantec PG licensed in the State of Tennessee.

3.3.1 Drilling

The temporary well borings were advanced by Stantec drillers licensed in Tennessee using HSA techniques in general accordance with American Society for Testing and Materials [ASTM] D6151: *Standard Practice for Using Hollow-Stem Augers for Geotechnical Exploration and Soil Sampling*. Drilling details are reported in the KIF Plant Exploratory Drilling SAR.

The additional boring locations near the temporary well locations were advanced by Hawkston Drilling, LLC, licensed in Tennessee, using a direct-push technology rig. The borings were advanced from the ground surface through the CCR materials to the targeted depth within the uppermost foundation soil for

sample collection and to identify the interface between the CCR materials and the foundation soil. Drilling details are reported in the KIF Plant Exploratory Drilling SAR.

The CCR material characteristics investigation temporary well and boring locations are shown on Exhibit A.1 in Appendix A.

3.3.2 CCR Material Sampling

During advancement of the boring, a Stantec Tennessee-licensed PG prepared field subsurface logs using a mobile data collection platform. Inputs included a description of subsurface lithology, sample recovery, color using the Munsell Soil Color Charts and other relevant parameters as required by the SAPs and TIs. As part of the logging process, each sample was photographed by FSP with sample interval data presented on a white board. Analytical and duplicate samples were collected from the CCR material characteristics investigation borings and documented in the *Daily Field Activity Log* and *COC*. A list of the CCR material samples are provided on Table B.1 in Appendix B. Split CCR material samples collected by CEC are also identified in Table B.1.

So that sufficient volume was available for CCR material sampling and other exploratory drilling investigation sampling activities, samples from the same depth intervals at the “a” and “b” boring locations were combined at boring locations KIF-B01a and KIF-B01b, KIF-B02a and KIF-B02b, and KIF-B03a and KIF-B03b (e.g., the sample from 36.5 to 38.5 ft bgs from KIF-B01a was combined with the sample from 36.5 to 38.5 ft bgs from KIF-B01b). Sufficient sample volume was available from boring KIF-B04a for analysis, so an additional boring at this location was not necessary and this boring became boring location KIF-B04. The samples were homogenized for CCR material analysis as described below.

The FSP typically collected approximately a two-foot grab sample from the midpoint of each five-foot boring interval where sampling was planned based on recovery. The collected sample was placed in clean, resealable bags and homogenized using gloved hands and when necessary, clean, disposable, or decontaminated sampling tools. The samples from borings KIF-B01a and KIF-B01b were homogenized and identified as KIF-B01; KIF-02a and KIF-02b were homogenized and identified as KIF-B02; and KIF-03a and KIF-03b were homogenized and identified as KIF-B03. CCR material for the sample intervals at the “a” locations (KIF-B01a, KIF-B02a, and KIF-B03a) were collected in a new, clean plastic bag and placed on ice within 15 minutes. The sample intervals remained on ice until they could be homogenized with the second sample interval at the “b” locations (KIF-B01b, KIF-B02b, and KIF-B03b). Once the sample was sufficiently homogenized, an aliquot of the homogenized sample and deionized water was used to create a paste for measurement of the CCR material pH with the ExTech ExStik 110 pH meter according to Stantec Operating Procedure – Rev 1. The measurements were recorded on the *Soil pH Data Form* within 15 minutes after creating the CCR material paste.

Afterwards, the CCR material sample was placed in an appropriate laboratory-supplied sample jar. CCR material samples were collected in accordance with ENV-TI-05.80.50, *Soil and Sediment Sampling.* Sample containers were labeled and handled in accordance with ENV-TI-05.80.02, *Sample Labeling and Custody*. FSP secured caps on each bottle and attached a custody seal across the cap before placing the sample container in a cooler with ice (within 15 minutes of sample collection) for transport to the

laboratory. QC samples were collected in accordance with ENV-TI-05.80.04, *Field Sampling Quality Control.*

The samples were analyzed for CCR-related constituents listed in Appendices III and IV of Title 40 of the Code of Federal Regulations Part 257 (40 CFR Part 257). In addition, five inorganic constituents listed in Appendix I of Tennessee Rule 0400-11-01-.04 and not included in the 40 CFR 257 Appendices III and IV were analyzed to maintain continuity with the TDEC environmental programs. These additional TDEC Appendix I constituents included copper, nickel, silver, vanadium, and zinc. The combined federal CCR Appendices III and IV constituents and TDEC Appendix I inorganic constituents are hereafter referred to as "CCR Parameters." In addition to the CCR Parameters, total organic carbon, iron, and manganese were added as specific parameters of interest to be analyzed per the CCR Materials Characteristics Investigation SAP. Also Synthetic Precipitation Leaching Procedure analyses were performed for metals and radiological parameters.

The CCR material analytical data for CCR Parameters and additional parameters of interest are presented in Tables B.2 and B.3, respectively, in Appendix B. The field pH data are summarized in Table B.4.

3.3.3 Pore Water Gauging and Sampling

The following sections present temporary well data collection and sampling procedures used during the CCR material characteristics investigation. The pore water sampling activities were conducted at the KIF Plant on April 9 through 12, 2019, following temporary well installation and development activities. Temporary well installation and well development information are reported in the KIF Plant Exploratory Drilling SAR.

3.3.3.1 Pore Water Level Measurements

Static pore water levels were measured at the five temporary wells in accordance with ENV-TI-05.80.44, *Groundwater Level and Well Depth Measurement* prior to sampling. On April 9, 2019, static water level readings were measured and recorded to the nearest 0.01 feet from a reference point on the top of each polyvinyl chloride well casing using an electronic water level indicator. Water level indicator probes were decontaminated prior to the first use and between measurements, and the decontamination was documented as specified in ENV-TI-05.80.05, *Field Sampling Equipment Cleaning and Decontamination*. Depth to pore water measurements were recorded on a *Water Level Measurement Form*. Pore water level data are shown in Table B.5 in Appendix B.

3.3.3.2 Pore Water Purging and Sampling

Analytical and field duplicate pore water samples were collected from the five temporary wells during a single sampling event. The temporary wells were purged using non-dedicated bladder pumps with dedicated tubing and low-flow purging and sampling techniques as specified in ENV-TI-05.80.42, *Groundwater Sampling*. Analytical and duplicate samples were collected from the temporary wells and

documented in the *Daily Field Activity Log* and *COC* as shown on Table B.6 in Appendix B. Split pore water samples collected by CEC are also identified in Table B.6.

During the purging process, water quality field parameters including pH, specific conductance, temperature, ORP, and DO were measured using water quality meters (YSI ProPlus with flow-through cell) and recorded on field forms. Depth to water and turbidity were measured and recorded using decontaminated electronic water-level indicators (Heron Dipper-T) and calibrated turbidimeters (Hach 2100Q). Water quality parameters were measured and recorded on a *Water Sampling Form* during purging until readings were stabilized as specified in the SAP and/or applicable TI. Well purging was considered complete when three consecutive readings met the following stabilization criteria:

- pH – ± 0.1 Standard Units
- Specific Conductance – ± 5% microSiemens per centimeter
- Turbidity – Less than 10 Nephelometric Turbidity Units (NTUs) or ± 10% for values above 10 NTUs
- DO – Less than 0.5 milligrams per Liter (mg/L) or ± 10% for values above 0.5 mg/L.

After water quality stabilization criteria were achieved, the final water quality parameter results were recorded, purging was discontinued, and a sample was collected as specified in the SAP. Final water quality parameter results are shown in Table B.7 in Appendix B.

Laboratory-provided, pre-preserved sample containers were filled directly from the pump discharge line with the exception of the dissolved metals samples, which were collected via a 0.45-micron disposable inline filter attached to the end of the discharge line to field filter the sample. FSP wore new, clean nitrile gloves when handling sample containers and did not touch the interior of containers or container caps. New gloves were used when handling each sample. When filling sample bottles, care was taken to minimize sample aeration (i.e., water was directed down the inner walls of the sample bottle) and to avoid overfilling and diluting preservatives. Each sample bottle was capped before filling the next bottle. Following completion of sampling, final turbidity measurements were made.

Sample containers were labeled and handled in accordance with ENV-TI-05.80.02, *Sample Labeling and Custody*. FSP secured caps on each bottle, attached a custody seal across the cap, and placed in a cooler on ice within 15 minutes of collection. QC samples were collected in accordance with ENV-TI-05.80.04, *Field Sampling Quality Control*

Pore water samples were analyzed for CCR Parameters and additional parameters of interest as defined in Section 3.3.2; the pore water analytical data are presented in Tables B.8 and B.9, in Appendix B.

3.4 INVESTIGATION DERIVED WASTE

Investigation derived waste (IDW) generated during the CCR material characteristics investigation included:

- CCR material cuttings
- Temporary well purge water
- Used calibration solutions
- Decontamination fluids
- Personal protective equipment (PPE)
- General trash.

IDW was handled in accordance with ENV-TI-05.80.05, *Field Sampling Equipment Cleaning and Decontamination* and ENV-TI-05.80.42, *Groundwater Sampling* (purge water); the KIF Plant-specific waste management plan; and local, state, and federal regulations. Transportation and disposal of IDW was coordinated with TVA Plant facility management. CCR material cuttings not kept for laboratory analysis, temporary well purge water, used calibration solutions, and decontamination fluids were managed as authorized by KIF Plant facility management and in accordance with the CCR Material Characteristics SAP. Used disposable PPE (e.g., nitrile gloves) and general trash generated throughout the day were placed in garbage bags and disposed of in a general trash dumpster onsite at the end of each day.

3.5 SAMPLE SHIPMENT

Samples were packed and transported under *COC* procedures as specified in ENV-TI-05.80.06, *Handling and Shipping of Samples*. The samples were delivered via courier to TestAmerica in Nashville, Tennessee and then subsequently shipped to St. Louis, Missouri (radium samples only), and to Pittsburgh, Pennsylvania (all other analytes). TestAmerica submitted sample receipt forms to EnvStds for review and confirmation.

3.6 VARIATIONS

The proposed scope and procedures for the CCR material characteristics investigation were outlined in the SAP, QAPP, and applicable TVA TIs and ASTM standards, as detailed in the sections above. Variations in scope or procedures discussed with TDEC and/or TVA, changes based on field conditions, or additional field sampling performed to complete the scope of work in the SAPs are described in the following sections. As discussed below, these variations do not impact the overall usability and representativeness of the dataset provided in this SAR for the CCR materials characteristics investigation at the KIF Plant.

3.6.1 Variations in Scope

Variations in scope from the SAP are provided below.

- After the completion of drilling and laboratory testing of samples from the temporary well borings, review of the data showed that borings KIF-TW01 through KIF-TW04 did not reach the foundation soils as originally logged in the field. These borings were inadvertently terminated within the CCR. Therefore, the supplemental direct push borings were added to extend the material profiles into the foundation soils and obtain the deeper samples adjacent to temporary wells KIF-TW01 through KIF-TW04. During the supplemental drilling, boring KIF-B04b was determined not to be necessary since adequate information and sample volume were obtained from boring KIF-B04a.

3.6.2 Variations in Procedures

Variations from the SAP, QAPP, and applicable TVA TI procedures occuring in the field are provided below.

- CCR material pH measurements for the samples collected from KIF-TW05 on November 13, 2018 were obtained after the analytical samples were placed in the sample containers rather than before; however, the pH was measured on the homogenized sample in accordance with the SAP.
- The sample ID nomenclature of the field blank sample collected on February 8, 2019 during CCR material sampling varied from the QAPP; however, this variance did not impact assessment of data quality during data validation.
- Photographs of boring cores from borings KIF-TW03a and KIF-TW03b are not available. These borings were terminated due to refusal at depths of 15.3 and 13.5 feet, respectively, and no analytical samples were submitted to the laboratory.

4.0 SUMMARY

The data presented in this report are from the CCR material characteristics investigation at the KIF Plant. The scope of work during this investigation included drilling five temporary well borings and seven additional borings to collect CCR material and pore water analytical samples for analysis of CCR Parameters and additional parameters of interest.

A summary of boring and temporary well locations drilled during this investigation is presented in Table 1. A total of 54 CCR material samples, including four duplicate samples, were collected from the five temporary well borings and the seven additional borings for analysis of CCR Parameters and additional parameters of interest. A summary of the CCR material samples collected during this investigation are presented in Table B.1, and sample analytical data are presented in Tables B.2 and B.3, respectively. The field pH data are summarized in Table B.4.

Following temporary well installation and development, pore water levels were measured prior to sampling, and five pore water samples and one duplicate sample were collected from the five temporary wells. Water quality parameters were recorded during well purging. Stabilization criteria for pH, specific conductance, turbidity, and DO were achieved at each sampling location. Pore water level measurements and a summary of the pore water samples collected are presented in Tables B.5 and B.6, respectively. The final pore water quality parameter measurements prior to initiating sample collection are presented in Table B.7. Pore water analytical data for CCR Parameters and additional parameters of interest are presented in Tables B.8 and B.9.

CCR material and pore water analytical data were reported by TestAmerica and validated by EnvStds.

Stantec has completed a CCR material characteristics investigation at the KIF Plant in Harriman, Tennessee, in accordance with the CCR Material Characteristics SAP as documented herein. The data collected during the investigation are usable for reporting and evaluation in the EAR and meet the objectives of the TDEC Order EIP. The CCR materials characterization data will be evaluated along with data collected under other TDEC Order SAPs, including but not limited to, the exploratory drilling investigation, as well as data collected under other State and CCR programs. This evaluation will be provided in the EAR.

APPENDIX A - EXHIBITS

Exhibit No.

A.1

Title

Temporary Well and Boring Location Map

Client/Project

Tennessee Valley Authority
Kingston Fossil Plant (KIF) TDEC Order

Project Location

Roane County, Tennessee

175668043

Prepared by DMB on 2020-05-20
Technical Review by RN on 2020-05-20

0 200 400 600 800 Feet

1:2,400 (At original document size of 22x34)

Legend

- Boring
- Drilled and Abandoned Borehole
- Temporary Well
- 2018 Imagery Boundary
- CCR Unit Area (Approximate)
- Engineered Wetlands (Approximate)
- Polishing Pond (Approximate)

Notes

1. Coordinate System: NAD 1983 StatePlane Tennessee FIPS 4100 Feet
2. 2017 Imagery provided by TVA and flown by Tuck Mapping on March 16, 2017; 2018 Imagery provided by TVA and is dated September 12, 2018.
3. Temporary Well locations shown correspond to survey data provided by the RLS Group on May 15, 2019.
4. Borings surveyed by TVA on January 9, 2020.
5. As-drilled boring location not surveyed. Horizontal coordinates based on proposed boring location.
6. Adjacent boring locations shown as single boring symbol due to close proximity.

1. Field and laboratory quality control sample results except for field duplicates are not included in report tables but were used for data validation.
2. CEC collected split samples from KIF-TW04 at depth intervals of 11.5-13.5 and 21.5-23.5 feet below ground surface

Notes:
Please note that units have been converted automatically in this table, and significant figures may not have been maintained.

<0.03	analyte was not detected at a concentration greater than the Method Detection Limit
-	parameter not analyzed / not available
ft	feet below ground surface
ID	identification
J	quantitation is approximate due to limitations identified during data validation
mg/kg	milligrams per kilogram
SPLP	Synthetic Precipitation Leaching Procedure
SU	Standard Unit
U*	this result should be considered “not detected” because it was detected in an associated field or laboratory blank at a similar level
ug/L	micrograms per Liter
UJ	this compound was not detected, but the reporting or detection limit should be considered estimated due to a bias identified during data validation
UR	Unreliable reporting or detection limit; compound may or may not be present in sample.

1. Level of review is defined in the Quality Assurance Project Plan.

Other Graphics

Symbol	Description
	Denotes environmental analytical sample interval
	Denotes SS sample interval
	Denotes ST sample interval
	Denotes DP sample interval
	Denotes RS sample interval
	Denotes RC sample interval
	First water level reading
	Second water level reading

Common Abbreviations

Abbreviation	Definition
DP	Direct Push
HA	Hand Auger
HSA	Hollow Stem Auger
N/A	Not Applicable
NR	Not Recorded
RC	Rock Core
RQD	Rock Quality Designation
RS	Rotary Sonic
SS	Split Spoon
ST	Shelby Tube
WH	Weight of Hammer
WR	Weight of Rod

General Notes

The boring logs include sample numbering used during drilling. For assigned Environmental Analytical Sample ID numbers, see relevant Environmental Chain-of- Custody forms from the drilling date range listed on each log.

For pH readings and additional field data, see applicable field documentation (e.g., Soil pH Data Form) from the drilling date range listed on each log.

1.0 INTRODUCTION

Stantec Consulting Services Inc. (Stantec) has prepared this Sampling and Analysis Report (SAR) on behalf of the Tennessee Valley Authority (TVA) to document activities related to a Material Quantity Assessment (MQA) at TVA's Kingston Fossil (KIF) Plant located in Harriman, Tennessee (see Exhibit A.1, Appendix A).

The purpose of the MQA is to use historical data supplemented with information collected for other TDEC Order SARs to perform three-dimensional modeling of certain coal combustion residuals (CCR) units at the KIF Plant and estimate CCR material quantities and other properties in support of fulfilling the requirements for the Tennessee Department of Environment and Conservation (TDEC) issued Commissioner's Order No. OGC15-0177 (TDEC Order) to TVA (TDEC 2015). The TDEC Order sets forth a "process for the investigation, assessment, and remediation of unacceptable risks" at TVA's coal ash disposal sites in Tennessee.

The purpose of this SAR is to document the three-dimensional modeling work completed during the MQA. This SAR is not intended to provide conclusions or evaluations of results. The scope of the MQA activities represented herein was conducted pursuant to the Material Quantity Sampling and Analysis Plan (SAP) (Stantec 2018b) and is part of a larger environmental investigation at the KIF Plant. The data provided in this SAR are not inclusive of other programmatic data that exist for this site. The evaluation of the results will consider other aspects of the environmental investigation, including data collected under other State and/or CCR programs and be presented in the Environmental Assessment Report (EAR).

The MQA activities discussed herein were performed in general accordance with the following documents developed by TVA to support fulfilling the requirements of the TDEC Order at the KIF Plant:

- *Material Quantity SAP* (Stantec 2018b)
- *Environmental Investigation Plan* (EIP) (TVA 2018)
- *Exploratory Drilling (EXD) SAP* (Stantec 2018c)
- *Quality Assurance Project Plan* (Environmental Standards, Inc. 2018).

2.0 OBJECTIVE AND SCOPE

The objectives of the MQA, conducted pursuant to the Material Quantity SAP, are to describe CCR unit geometry, CCR material quantity, phreatic elevations, and subsurface conditions for certain CCR units at the KIF Plant in response to the TDEC Order. The Material Quantity SAP included evaluation of the following CCR units: Interim Ash Staging Area, Sluice Trench and Area East of Sluice Trench, and Stilling Pond (MQA Study Area). This scope does not include the Kingston Recovery Project (KRP) Ash Landfill or the Peninsula Disposal Area.

The approach for the MQA SAR was to develop three-dimensional models of the MQA Study Area using data from existing borings installed under different environmental or geotechnical programs, as well as pre-construction topographic information for the MQA Study Area. The existing information was supplemented with data from borings drilled per the EXD SAP.

The scope of work consisted of the following tasks:

- Developing three-dimensional subsurface models from ground surface to bedrock using boring elevation data and pre-construction topographic information
- Developing a cross section location map and cross sections showing the modeled dikes and surfaces
- Identifying additional information needed to complete the objectives of the Material Quantity SAP.

Details of the completed MQA work are presented in the following sections. These activities were carried out following the completion of borings drilled per the EXD SAP. Details of the drilling activities are provided in the EXD SAR.

3.0 PHYSICAL SETTING AND SITE HISTORY

3.1 CCR MATERIAL PLACEMENT SITE HISTORY

The KIF Plant is located at the confluence of the Emory River and Clinch River (Exhibit A.1, Appendix A). Prior to the construction of Watts Bar Dam, Swan Pond Creek followed a meandering course through the KIF Plant footprint and discharged to the Emory River (Exhibit A.2, Appendix A); however, the construction of Watts Bar Dam circa 1942 created a backwater area that impounded Swan Pond Creek along with the Emory and Clinch Rivers.

The KIF Plant was initially constructed between 1951 and 1954, including starter dikes labeled North Dike and East Dike shown on Exhibit A.3 (Appendix A). CCR was initially sluiced to the Initial Ash Disposal Area which was initially bounded by the North Dike and East Dike (refer to Attachments B.1 and B.2, Appendix B; TVA 1981 and 1958; Exhibit A.3, Appendix A). By 1959, Dikes B (interior dike) and C (exterior dike) were constructed to form the Ash Disposal Area (refer to Attachments B.2 and B.3, Appendix B; TVA 1958 and 1977a; Exhibit A.3, Appendix A). The CCR sluiced into these ponds formed what would later be labeled the “Hydraulically Placed Ash” horizon. In 1965, the Initial Ash Disposal Area reached sluiced CCR placement capacity and CCR was subsequently directed to the Ash Disposal Area which was progressively filled from south to north (AECOM 2009). In 1968, Dike B, an interior dike, was constructed with CCR material along the toe of the railroad embankment on the west side of the Initial Ash Disposal Area (refer to Exhibit A.3, Appendix A). Between 1976 and 1978, TVA raised Dike C from elevation 748 feet to 765 feet to provide additional freeboard and constructed a divider dike to form the Stilling Pond to allow final particles to settle out before discharging to the Watts Bar Reservoir (refer to Attachments B.4 and B.5, Appendix B; TVA 1977b and TVA 1977c; Exhibit A.3, Appendix A). The Metal Cleaning Ponds were also constructed in the footprint of the closed Initial Ash Pond during this time period (refer to Attachments B.4 and B.5, Appendix B; TVA 1977b and 1977c; Exhibit A.3, Appendix A).

In 1983, TVA constructed Dike D (interior dike) in a southwest-to-northeast direction. The construction of Dike D roughly reduced the size of the Ash Disposal Area by half as part of a transition to dredge cell operations (refer to Attachment B.6, Appendix B; TVA 2001; Exhibit A.3, Appendix A). In 1984, TVA began sluicing fly ash, bottom ash, and other plant process waters into a sluice trench excavated into CCR that discharged to the Ash Disposal Area. Fly ash and bottom ash were then excavated from the sluice trench, dredged from the Ash Disposal Area, and transported to Dredge Cell Nos. 1, 2, and 3 for stacking (refer to Attachment B.6, Appendix B; TVA 2001; Exhibit A.3, Appendix A). The dredge cells were permitted by TDEC as a Class II Solid Waste Landfill (USEPA 2009).

Seeps were noted on the west slope of Dredge Cell Nos. 1, 2, and 3 from 2003 through 2008. Per the KIF Plant’s Routine Handling Operations and Maintenance Support Document (TVA 2011), quarterly seep inspections were conducted and documented and actions to address identified seeps were determined, prioritized, and executed. Instability was noted along the western limits of Dredge Cell Nos. 1, 2, and 3, which resulted in repairs. An Emergency Dredge Cell was constructed to stage CCR while the repairs were being made (TVA 2006).

In December 2007, the Peninsula Disposal Area was permitted by TDEC for the management of wet gypsum. A permit modification was later approved, allowing for the management of bottom ash and fly ash in the Peninsula Disposal Area along with gypsum

In December of 2008, a failure initiated in the northwestern corner of Dredge Cell No. 2, resulting in significant displacement of CCR to the Emory and Clinch Rivers. This resulted in TVA and the USEPA signing an Administrative Order and Agreement on Consent (USEPA 2009) that provided the regulatory framework for response and recovery actions under the Comprehensive Environmental Response, Compensation, and Liability Act. TDEC also issued a Commissioner's Order to TVA (TDEC 2009) requiring the comprehensive assessment, clean-up and restoration of areas impacted by the release. In accordance with these USEPA and TDEC Orders, TVA submitted plans and reports associated with the response and recovery projects to USEPA for review and approval and USEPA consulted TDEC during the review process (TVA 2015b).

TVA initiated emergency response actions and recovery operations the day of the failure on December 22, 2008 and continued through 2015. These included river dredging, environmental sampling, embayment restoration, and construction of the KRP Landfill. The KRP Landfill was constructed with a perimeter wall containment system to withstand design earthquake loads (TVA 2015b).

As a part of removal actions and per approvals from TDEC (TVA 2015a), the Metal Cleaning Ponds were closed so that the closed Initial Ash Pond could serve as a temporary staging area for CCR during river dredging operations and subsequent construction of the KRP Landfill. A delineation layer of stone and geotextile fabric was placed over the Initial Ash Pond subgrade prior to staging CCR (TVA 2009). This staging area corresponds to the Interim Ash Staging Area.

Staged CCR above the delineation layer was eventually removed from the Interim Ash Staging Area and placed in the Peninsula Disposal Area (AECOM 2016a). TVA completed capping and closure of the KRP Landfill in 2015 and the Interim Ash Staging Area in 2016 (Attachment B.7, Appendix B; AECOM 2018a).

In 2015, TVA initiated the transition from wet to dry CCR handling which included the following activities:

- Construction of temporary free-standing containers and the Bottom Ash Dewatering Plant to dewater bottom ash
- Capping and closure of the sluice trench area of the Sluice Trench and Area East of Sluice Trench as documented in AECOM (2018b and 2019a)
- Construction of a geomembrane-lined water quality channel and Polishing Pond to convey and treat process water prior to discharging to National Pollutant Discharge Elimination System (NPDES) Outfall 001.
- Construction of conveyance piping from the Polishing Pond outlet to NPDES Outfall 001
- Capping and closure of the Stilling Pond as documented in Stantec (2017 and 2018a).

Capping and closure of the Stilling Pond involved the removal of free water, partial excavation of Dike C for borrow material, and the construction of a cap with a geomembrane liner and vegetative soil layer as documented in Stantec (2017 and 2018a). TVA completed the construction of a seepage collection system and reverse graded filter at the East Dike in 2017. The closure of Sluice Trench and Area East of Sluice Trench CCR management unit was completed in 2018 with the construction of a cap with a geomembrane and vegetative soil layer along the East Dike in 2018 (AECOM 2018b and 2019a).

3.2 EXISTING CONDITIONS

CCR material is present at the KIF Plant in several individual areas including the three CCR management units in the MQA Study Area (Interim Ash Staging Area, Sluice Trench and Area East of Sluice Trench, and Stilling Pond), KRP Ash Landfill, and Peninsula Disposal Area. These CCR management units are shown on Exhibit A.1 (Appendix A). CCR generated at the KIF Plant is currently placed in the Peninsula Disposal Area which is the remaining active CCR unit at the KIF Plant.

3.3 PRIOR MATERIAL QUANTITY ASSESSMENTS

Previous material quantity assessments were completed by TriAD Environmental Consultants, Inc. (TriAD) of Nashville, Tennessee as part of their Historical Ash Volume Calculations (TriAD 2017a and 2017 b). The Historical Ash Volume Calculations by TriAD were completed for the MQA Study Area as well as the KRP Ash Landfill and Peninsula Disposal Area. The results of their calculations for the Interim Ash Staging Area and the Stilling Pond will be compared with Stantec's evaluation results in the EAR.

4.0 THREE-DIMENSIONAL MODEL METHODOLOGY

Three-dimensional models of the MQA Study Area were developed to depict subsurface conditions from the ground surface to bedrock using AutoDesk® AutoCAD® Civil 3D software (Civil 3D). Elevation data including contours and boring elevations were imported into Civil 3D to model the three-dimensional surface of specific layers that comprise the CCR management units within the MQA Study Area using a surface triangulation method. Refer to Autodesk (2021) for more information regarding Civil 3D surface triangulation. The approach used to model the CCR management units within the MQA Study Area is summarized below. The Interim Ash Staging Area and Sluice Trench and Area East of Sluice Trench were incorporated into one model since they are adjacent CCR management units not divided by a feature such as a dike or perimeter wall.

1. Pre-Construction Topography: The approach to modeling the ground surface prior to the construction of the dikes and placement of CCR was to identify and evaluate historic topographic drawings with pre-construction contours for use in the pre-construction surface. Topographic drawings that did not provide horizontal coordinates were deemed not usable since horizontal coordinates were required to georeference the drawing and spatially align it with other data sources. Boring elevation data was used to confirm the accuracy of the contours used in the pre-construction surface. If the elevation differences between the pre-construction contours from the drawing and the boring elevation data were considered negligible for the purposes of estimating CCR volumes, the borings were designated as confirmation borings and not imported into the surface to preserve the continuity of the pre-construction surface.

Topographic drawings with pre-construction contours evaluated for use in the pre-construction surface included the *1924 Aerial and Plane Table Survey by War Department* (AECOM 2009), the 1941 *United States Geologic Survey (USGS) Topographic Map of the Harriman Quadrangle* (USGS 1941) and TVA Drawing 10N400R4 (TVA 1958). With the exception of the 1*924 Aerial and Plane Table Survey by War Department* (AECOM 2009), the drawings provided horizontal coordinates that could be used to georeference the drawing and spatially align them with other data sources. Contour data from TVA Drawing 10N400R4 (Attachment B.2, Appendix B) was used to model the pre-construction surface since it provided 5-foot interval contours versus the 20-foot interval contours provided by USGS (1941), included coordinates for georeferencing, and included the starter dike alignments and other KIF Plant features.

The TVA Drawing was imported into Civil 3D as an image and georeferenced using the coordinates provided on the drawing. The contours shown on the drawing were digitized by tracing a three-dimensional polyline (3D polyline) over the contours and assigning an elevation coordinate to each 3D polyline which corresponded to the contour elevation shown on the drawing. The 3D polylines were used to model a three-dimensional surface of the pre-construction topography.

The pre-construction topographic information in low-lying areas below the water surface (represented by the 724-feet elevation contour) shown on TVA Drawing 10N400R4 (Attachment B.2, Appendix B) was supplemented with boring elevation data from the model input borings summarized in Table C.1 (Appendix C). Boring elevation data from confirmation borings summarized in Table C.1 (Appendix C)

were used to confirm the pre-construction topographic contours. Model input and confirmation data used to model and evaluate the pre-construction surface are summarized in Table C.1 (Appendix C). Model input and confirmation borings and the revised pre-construction topography used in the three-dimensional models are presented on Exhibit A.4 (Appendix A).

2. Starter Dike/Buttresses: In addition to topography information, TVA Drawings 10N400R4 (TVA 1958) and 10N400R6 (TVA 1977a) show cross sectional and design information for the North Dike, East Dike, and Dike C. The approximate locations of the starter dikes were digitized and modeled, using the design geometry presented on TVA Drawings 10N400R4 and 10N400R6, which are provided as Attachments B.2 and B.3 (Appendix B). The approximate locations of the starter dikes were also confirmed using boring information and topographic surveys.

The locations of the internal divider dikes and raised dike geometries were obtained from TVA Drawings 10N420R2 (TVA 1977b) and 10N421R1 (TVA 1977c) as presented on Attachments B.4 and B.5 (Appendix B).

3. Bottom of CCR Surface: For the purposes of the MQA, it was assumed that the bottom of CCR surface is equivalent to the pre-construction surface within the interior of the modeled dikes. Model input and confirmation data used to model and evaluate the bottom of CCR surface are summarized in Table C.1 (Appendix C). Exhibit A.5 (Appendix A) shows the bottom of CCR surface contours with the model input and confirmation borings.

4. Final Elevation Surface: Contours from the 2017 KIF Plant aerial survey (Tuck 2017) and supplemental 2018 as-built construction surveys for the East Dike (Attachment B.8, Appendix B; AECOM 2019b) and Stilling Pond (Attachment B.9, Appendix B; Stantec 2018e) capping projects, as shown on Exhibit A.6 (Appendix A) were used to model a composite final surface elevation of the MQA Study Area. Final grading for the East Dike and Stilling Pond closure projects was completed in 2018. The horizontal datum is Tennessee State Plane North American Datum of 1983, and the vertical datum is National Geodetic Vertical Datum of 1929. Model input data used to model the final elevation surface summarized in Table C.2 (Appendix C).

5. Top of CCR Surface: For the purposes of the MQA, the top of CCR surface for the Interim Ash Staging Area and Sluice Trench and Area East of Sluice Trench was developed by lowering the final elevation surface 24 inches which corresponds to the thickness of the Interim Ash Staging Area (refer to Attachment B.7) and Sluice Trench and Area East of Sluice Trench (refer to AECOM 2018b and 2019b) cap systems. The top of CCR surface in the Stilling Pond was modeled using hydrographic survey contours shown on TVA Drawing 81W404-03 (Attachment B.10, Appendix B, Stantec 2019d). The hydrographic survey contours were based on hydrographic surveys performed by TVA in 2012 and 2015 prior to the completion of the capping project.

The borings designated as confirmation borings summarized in Table C.3 (Appendix C) were used to evaluate the modeled top of CCR surfaces. Model input data and confirmation data used to model and evaluate the top of CCR surface are summarized in Table C.3 (Appendix C). Exhibit A.7 (Appendix A) shows contours from the modeled top of CCR surface with the confirmation borings.

6. Top of Bedrock Surface: Logs for borings installed as part of the EI discussed in the EXD SAR and other environmental and geotechnical programs were evaluated to identify which provided bedrock elevation boring data. Bedrock elevation boring data was imported into Civil 3D as point data to model a three-dimensional surface of the top of bedrock using a surface triangulation method. Imported bedrock elevation data is referenced herein as model input data. The Kriging interpolation method in Civil 3D was then applied to refine and smooth the bedrock surface. Model input data used to model the top of bedrock surface are summarized in Table C.4 (Appendix C). Exhibit A.8 (Appendix A) shows the top of bedrock surface contours and model input borings.

5.0 CROSS SECTIONS

A cross section location exhibit and five representative cross sections are provided as Exhibits A.9 through A.11 (Appendix A). The cross-section locations were intentionally selected to capture variations within each CCR management unit. The cross sections are on approximate 800-foot spacing. The modeled dikes and surfaces discussed in Section 4.0 are shown on the cross sections.

6.0 LIMITATIONS

The following items are limitations of the information presented herein:

- The topographic contours from TVA Drawing 10N400R4 (Attachment B.2, Appendix B) used to estimate the pre-construction and bottom of CCR material surface was generated by georeferencing historical data and digitizing the contours and should be considered approximate. In general, the topographic contours from TVA Drawing 10N400R4 correlated with historical and recent boring data.
- Documentation regarding the depth of cover placed over CCR material west and south of the capping limits within the Interim Ash Staging Area is limited.

7.0 SUMMARY

The information presented in this report is from the MQA at the KIF Plant. The scope of work for this MQA SAR included developing new three-dimensional models of the Study Area CCR management units using data from existing borings installed under different environmental or geotechnical programs and the EI, as well as pre-construction topographic information for the MQA Study Area. The existing information was supplemented with data from borings drilled per the EXD SAP. The scope of work included:

- Developing three-dimensional subsurface models from ground surface to bedrock based on existing and supplemental boring data and pre-construction topographic information
- Developing a cross section location exhibit and cross sections showing the modeled dikes and surfaces
- Identifying additional information needed to complete the objectives of the Material Quantity SAP.

Data and drawings used to develop the three-dimensional models are summarized in Section 4.0 and presented in the exhibits, attachments, and tables. A cross section location map and cross sections are presented in Section 5.0. Limitations of the three-dimensional models are presented in Section 6.0.

Stantec has completed development of three-dimensional models of the Study Area for the MQA at the KIF Plant in Harriman, Tennessee, in accordance with the Material Quantity SAP as documented herein. The three-dimensional models are usable for reporting and evaluation in the EAR and meet the objectives of the TDEC Order EIP. The three-dimensional models will be evaluated along with data collected under other TDEC Order SAPs, as well as data collected under other State and CCR programs and will be used to fulfill the requirements of the TDEC Order. This evaluation will be provided in the EAR.

- Cambrian Conasauga Shale
- Cambrian Rome Formation

ID = identification
TOR = top of rock
RQD = Rock Quality Designation
CCR = Coal Combustion Residuals

Notes

1. Coordinate System: NAD 1983 StatePlane Tennessee FIPS 4100 Feet
2. Vertical Datum: NGVD29
3. Imagery provided by Esri World Imagery
4. Model input data used to model the top of bedrock surfaces shown herein are summarized in Table C.5 (Appendix C).
5. During the construction of the Perimeter Containment Soil-Cement Stabilization, top of bedrock elevations were determined by a combination of predrilling (S&ME 2011) and trench excavations. This top of bedrock information is available for the entirety of the Stabilization alignment and the spacing between top of bedrock observations range from approximately 15 feet to 20 feet.
6. RQD value corresponds to upper 20 feet of rock core.
7. Geologic map corresponds to Moore, James L. et al (1993), "Geologic Map of The Harriman Quadrangle, Tennessee"

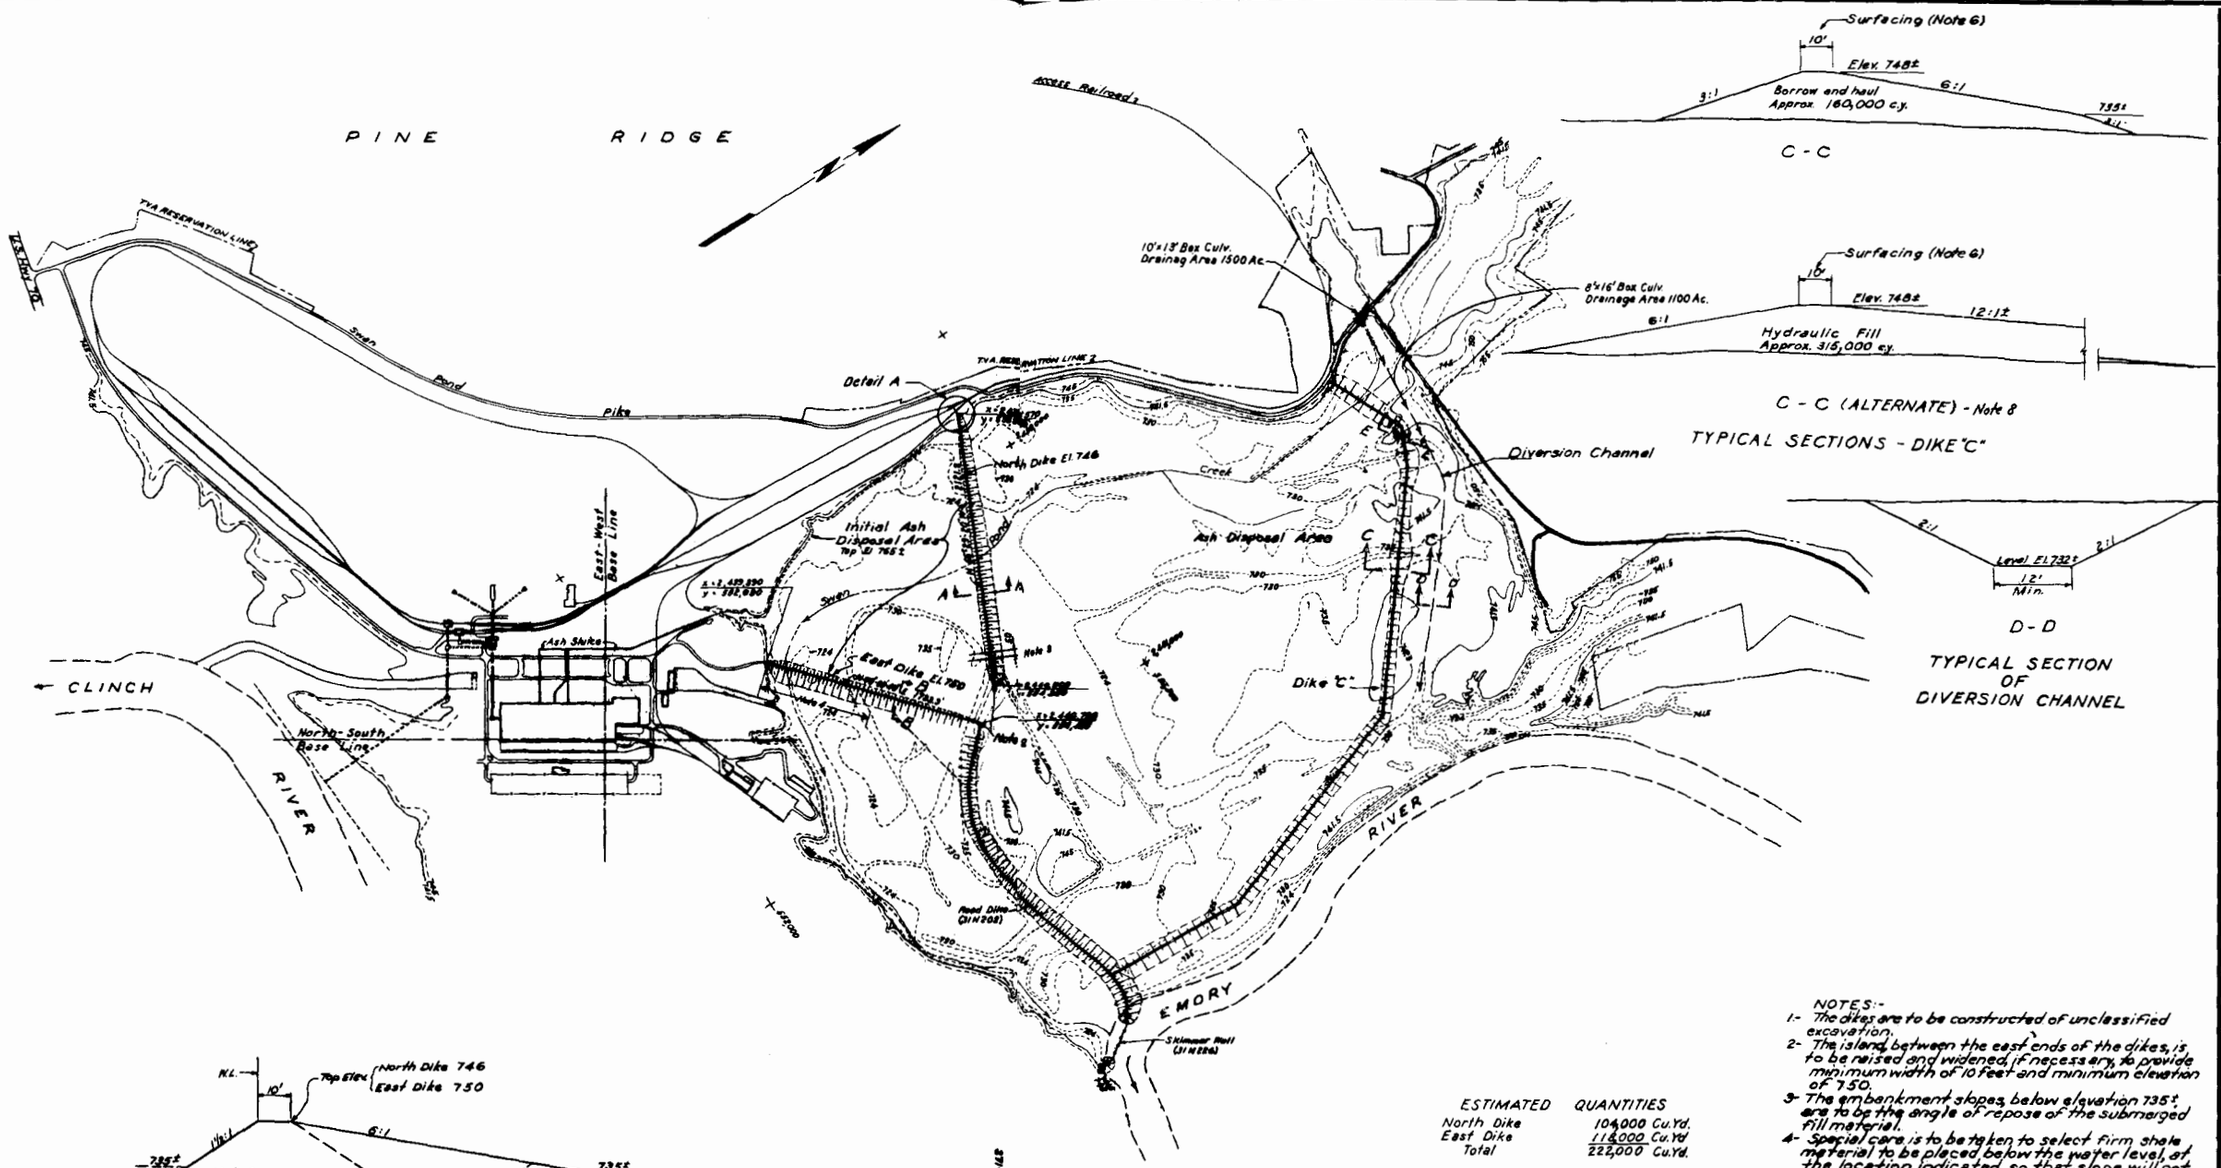
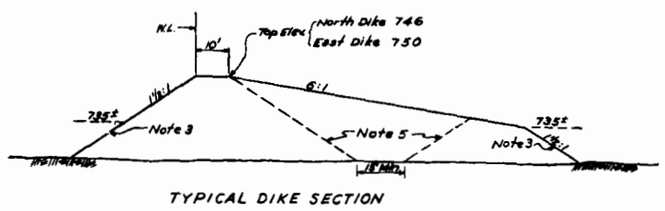
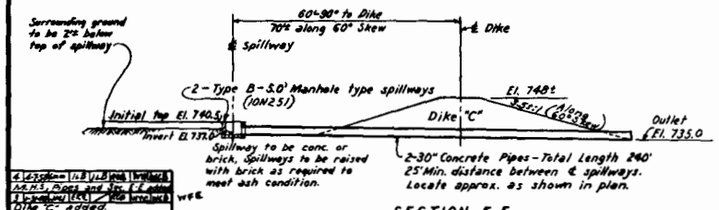
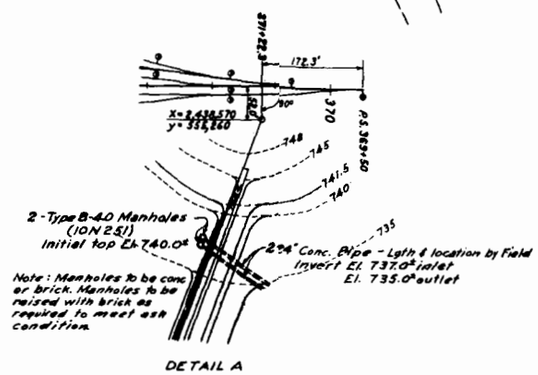
10N400









ESTIMATED QUANTITIES

North Dike	104,000 Cu.Yd.
East Dike	118,000 Cu.Yd.
Total	222,000 Cu.Yd.

NOTES:-

1- The dikes are to be constructed of unclassified excavation.
2- The island between the east ends of the dikes, is to be raised and widened, if necessary, to provide minimum width of 10 feet and minimum elevation of 750.
3- The embankment slopes below elevation 735± are to be the angle of repose of the submerged fill material.
4- Special care is to be taken to select firm shale material to be placed below the water level, at the location indicated, so that slope will not extend into the area of the intake channel.
5- Insofar as it is feasible and practical, the core of the east dike, as indicated, should be constructed of earth and fine material to provide a relatively impervious dam.
6- Top of Dike "C" to be surfaced with slag and ashes, 6" compacted thickness.
7- Quantities shown for Dike C are net fill for section shown and do not include shrinkage etc.
8- Section C-C is the minimum section to be used. The slopes shown for the hydraulic fill section are assumed and may be steeper if material can be placed on steeper slopes.
9- Remove existing dike for minimum width of 50ft. and to elevation 742 or lower after Dike C has been completed to at least elevation 745.

NOTES:

1. SOIL EXPLORATION AND LABORATORY TESTING IS RECORDED IN MEMORANDUM REPORT FROM GENE FARMER TO C.L. BUCHANAN, DATED NOVEMBER 3, 1975.
2. CIRCULAR-ARC STABILITY ANALYSIS SAFETY FACTORS FOR THE MEN DIKES BASED UPON AN EVALUATION OF THE SOILS INVESTIGATION REPORT ARE AS FOLLOWS:
   A. INITIAL CONSTRUCTION, EXTERIOR SLOPE: SAFETY FACTOR = 2.6
   B. INITIAL CONSTRUCTION, INTERIOR SLOPE: SAFETY FACTOR = 1.9
   C. OPERATING CONDITION WITH ASH AND WATER TO EL. 761, EXTERIOR SLOPE: SAFETY FACTOR = 2.7
   D. OPERATING CONDITION WITH ASH AND WATER TO EL. 761, INTERIOR SLOPE: SAFETY FACTOR = 1.6
3. ALL WORK TO BE IN ACCORDANCE WITH T.V.A SPECIFICATIONS UNLESS NOTED
4. ALL DIKE CONSTRUCTION SHALL BE IN ACCORDANCE WITH GENERAL CONSTRUCTION SPECIFICATION NO. G-9 FOR ROLLED EARTHFILL FOR DAMS AND POWER PLANTS. FILL COMPACTION SHALL BE AT LEAST 95% OF STANDARD MAXIMUM DENSITY AND FILL MOISTURE CONTENT SHALL BE WITHIN ±3% OF OPTIMUM MOISTURE CONTENT, AS DETERMINED BY THE CENTRAL SOILS LABORATORY.
5. FOUNDATION PREPARATION FOR EARTH EMBANKMENTS SHALL CONSIST OF REMOVING ORGANIC TOPSOIL, TO A DEPTH THAT WILL REMOVE ALL ROOTS, AND ALL PERVIOUS MATERIAL (RIPRAP, GRAVEL, CRUSHED STONE, COARSE ASH, ETC.), AND EXCAVATION SHALL CONTINUE TO A DEPTH THAT WILL SUPPORT HEAVY EARTH MOVING EQUIPMENT WITHOUT RUTTING INTO THE GROUND AND WITHOUT KNEADING THE GROUND SO AS TO REDUCE ITS STABILITY.
6. PIPE BACKFILL SHALL CONSIST OF IMPERVIOUS SOIL, FREE OF DEBRIS, WITH NO HARD LUMPS OR CLODS LARGER THAN 3" IN DIAMETER. COMPACTION SHALL BE BY HAND-HELD COMPACTORS TO A MINIMUM OF 1' ABOVE THE TOP OF THE PIPE. THE SOIL SHALL BE PLACED IN 6" LAYERS AND COMPACTED TO AT LEAST 95% OF STANDARD MAXIMUM DENSITY AS ESTABLISHED BY THE CENTRAL SOILS LABORATORY. BACKFILL MOISTURE SHALL BE CONTROLLED TO OBTAIN THE MAXIMUM PRACTICABLE DENSITY. THE BACKFILL SHALL BE PLACED SO AS TO MAINTAIN THE SAME ELEVATION ON BOTH SIDES OF THE PIPE.
7. THE DIVIDER DIKE SHALL BE CONSTRUCTED OF BOTTOM ASH. PLACEMENT OF THE UNDERWATER ASH FILL SHALL BE BY END DUMPING ALONG THE LENGTH OF THE DIKE. THE TOP SURFACE OF THE UNDERWATER DIKE JUST ABOVE THE WATER SHALL BE THOROUGHLY COMPACTED AND SCARIFIED BEFORE PLACING THE OVERLAYING ASH FILL. BOTTOM ASH FOR THAT PORTION OF THE DIVIDER DIKE ABOVE WATER SHALL BE PLACED IN NOT MORE THAN 9-INCH LAYERS, AND SHALL BE WELL COMPACTED WITH RUBBER TIRED HAULING EQUIPMENT.
8. CUT SLOPES ADJACENT TO EXISTING OR PROPOSED DIKES SHALL NOT BE EXCAVATED STEEPER THAN 3:1 AND TOP OF CUT SHALL BE A MINIMUM OF 20' FROM THE TOE OF ANY DIKE.
9. WHEN CONNECTING THE NEW DIKE TO THE OLD DIKE, EXTREME CARE SHALL BE USED TO INSURE AN IMPERVIOUS AND STABLE CONNECTION. THE EXISTING DIKES SHALL BE STRIPPED OF ALL VEGETATION, RIPRAP, GRAVEL, CRUSHED STONE, COARSE ASH AND OTHER PERVIOUS MATERIAL, BENCHED, AND SCARIFIED TO A MINIMUM DEPTH OF 6" AND COMPACTED SO AS TO FORM A BOND WITH THE NEW FILL. THE UTMOST CAUTION SHALL BE USED IN BENCHING THE EXISTING DIKE SLOPES SO AS NOT TO CREATE AN UNSTABLE CONDITION. SMALL BENCHES OF MINIMUM DEPTH SHALL BE USED.
10. GRASSING: CUT AND FILL SLOPES, AND DISTURBED AREAS SHALL BE SEEDED WITH TYPE RE MIXTURE (SPRING SEEDING) OR TYPE B (FALL SEEDING). IF COVER IS NEEDED PRIOR TO SEEDING DATES USE TYPE S FOR WINTER SEEDING AND TYPE 10N FOR SUMMER SEEDING. ALL AREAS ARE TO BE SEEDED, FERTILIZED, AND MULCHED IN ACCORDANCE WITH SECTIONS 180 AND 182.
11. RIPRAP IS TO BE PLACED AT THE LOCATIONS AS SHOWN. AT LEAST 50% OF THE RIPRAP SHALL CONSIST OF STONE OF A WEIGHT EQUAL TO OR GREATER THAN 150 LBS., AND IN ACCORDANCE WITH SECTION 830.
12. FILTER BLANKET SHALL BE 6" THICK AND IN ACCORDANCE WITH SECTION 831.
13. SUMMARY OF QUANTITIES: SEE DWG 2102H101
14. EARTH FILL COMPACTION IN CHEMICAL PONDS SHALL BE DONE WITH SHEEPSFOOT ROLLERS AND SHALL BE AT LEAST 95% OF STANDARD PROCTOR MAXIMUM DENSITY. FILL MOISTURE SHALL BE CONTROLLED TO ACHIEVE OPTIMUM COMPACTION.
15. SURFACING FOR THE EARTH FILL AROUND CHEMICAL PONDS SHALL BE 4" OF CRUSHED STONE, PER SECTION 210 OF THE T-I SPECS.
16. RIPRAP IN CHEMICAL PONDS SHALL BE 18" THICK, WITH A MINIMUM OF 50% BY WEIGHT, CONSISTING OF STONES AT LEAST 100 POUNDS EACH. RIPRAP SHALL CONFORM TO SECTION 830 OF THE T-I SPECS.

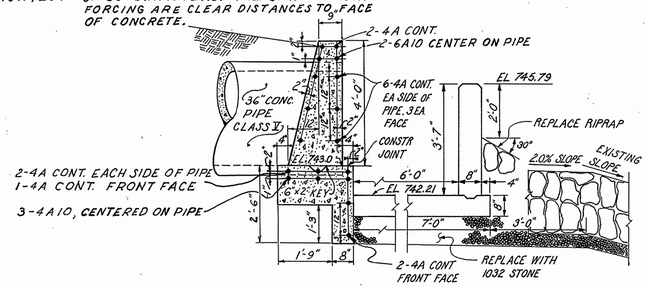
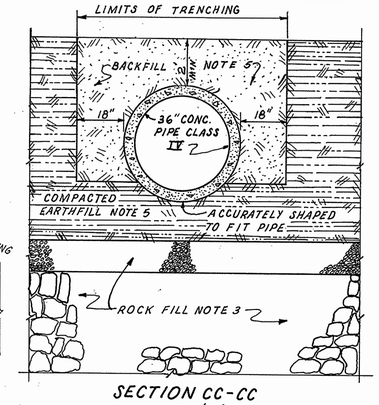
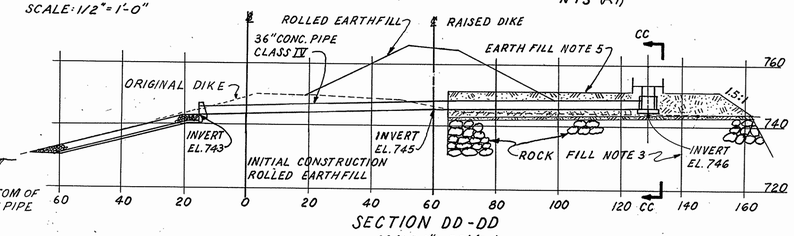
NOTE:
SPACER BARS BY FIELD
NOTE:
USE VERTICAL CONSTRUCTION JOINTS AT THIRD POINTS OF THE LENGTH WITH 6"x2" KEY. CHAMFER EXPOSED EDGES 3/4". LAP REINFORCING BARS A MINIMUM DISTANCE OF 36" DIAMETERS. DIMENSIONS TO REINFORCING ARE CLEAR DISTANCES TO FACE OF CONCRETE.



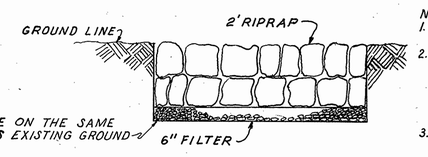
SECTION E-E
SCALE: 1/2"=1'-0"



SECTION CC-CC
NTS (R1)

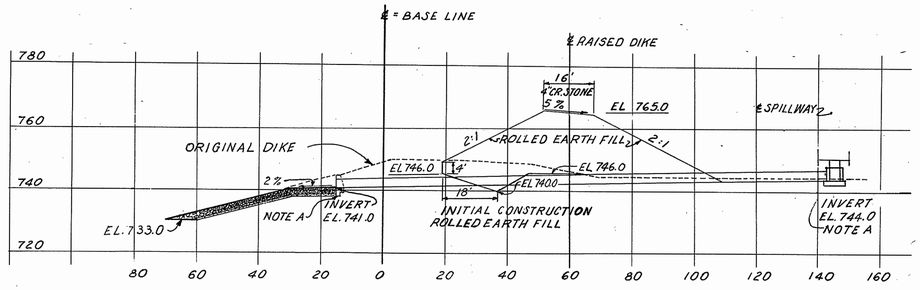


SECTION DD-DD
SCALE 1" = 20' (R1)



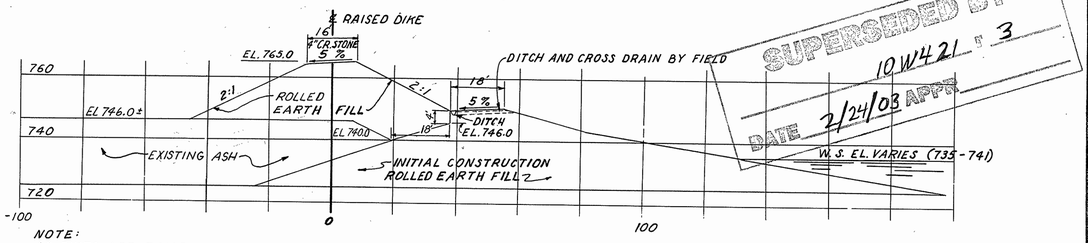
SECTION C-C
NOT TO SCALE

NOTES:
1. FOR ADDITIONAL NOTES SEE DWG 10N420. NOTES BELOW ARE FOR REVISION R1.
2. SPILLWAYS, OUTLET PIPES, AND HEADWALL WERE INSTALLED IN 1976. OUTLET PIPES ARE CRACKED AND JOINTS OPEN GENERALLY OVER HALF THE PIPE LENGTH TOWARD THE SPILLWAYS. ALL PIPES ARE TO BE REMOVED AND REPLACED. THE SPILLWAY BOXES AND HEADWALL ARE TO BE RAISED 2 FEET AND THE PIPES LAID TO NEW GRADE AS SHOWN ON SECTION DD-DD.
3. THE ROCKFILL SHOWN ON PLAN-DETAIL "A" AND SECTIONS DD-DD AND CC-CC IS THE ROCKFILL PLACED IN ACCORDANCE WITH THE REPORT FROM J. P. HILLIER STIVERS TO CIVIL ENGINEERING AND DESIGN BRANCH FILES, DATED AUGUST 27, 1976, COPIES TO DIVISION OF CONSTRUCTION (H.H. MULL AND GENE FARMER) AMONG OTHERS. THE SPILLWAY BOXES AND PART OF THE OUTLET PIPE LENGTHS WERE INSTALLED ON THE ROCKFILL.
4. COMPACTED EARTHFILL IS TO BE PLACED ON THE ROCKFILL TO PROVIDE NEW FOUNDATION FOR THE SPILLWAY BOXES AND OUTLET PIPES. BEFORE THE EARTHFILL IS PLACED, THE ROCKFILL SHALL BE TESTED FOR SOUNDNESS. SEVERAL PASSES OF HEAVY EARTH-MOVING EQUIPMENT SHALL BE MADE ON THE ROCKFILL TO ENSURE THAT THE ROCKFILL IS STABLE AND NON-SETTLING. IT MUST BE ASSURED THAT THERE IS A MINIMUM OF 6" OF COMPACTED CRUSHED STONE ON THE ROCKFILL TO PREVENT MIGRATION OF COMPACTED EARTHFILL INTO ROCKFILL.
5. COMPACTED EARTHFILL SHALL BE PLACED TO 2 FEET ABOVE TOP OF PIPE IN ACCORDANCE WITH NOTE 4 ON DWG 10N420, TRENCHED AS SHOWN ON SECTION CC-CC, THE OUTLET PIPES LAID, AND THE PIPES BACKFILLED IN ACCORDANCE WITH NOTE 6 ON DWG 10N420. THE SPILLWAY BOXES SHALL BE RESET ON THE COMPACTED EARTHFILL AND A NEW HEADWALL CONSTRUCTED. THE EARTHFILL AROUND THE SPILLWAY BOXES SHALL BE REMOVED TO EL 749 OR LOWER WHEN THE INSTALLATION OF THE SPILLWAYS, PIPES, AND HEADWALL IS COMPLETE. THE EARTHFILL SHALL BE REMOVED FROM A STRIP 10' EACH SIDE OF THE CENTERLINE OF THE SPILLWAY BOXES AND EXTENDING COMPLETELY BETWEEN ALL SPILLWAYS.



SECTION B-B (PIPE DETAILS SUPERSEDED SEE SECT. DD-DD (R1))
SCALE: 1"=20' (10N420)

NOTE A:
STRUCTURES TO BE ON FIRM FOUNDATION. IF NATURAL GROUND IS NOT FIRM, REMOVE TO DEPTH OF 4' AND REPLACE WITH COMPACTED FILL.



NOTE:
AS DIKES ARE RAISED, THE FIELD SHALL PROVIDE DRAINAGE FROM THE TOP AND OUTSIDE SLOPES OF THE DIKES THAT WILL CONTROL EROSION OF THE DIKES.

SURVEY CONTROL NOTE:

A GLOBAL POSITIONING SYSTEM (GPS) BASE STATION HAS BEEN ESTABLISHED AND TRANSFORMATION PARAMETERS DETERMINED BY TVA USING SELECTED SURVEY CONTROL MONUMENTS. CONTACT WITH TVA SURVEYING DEPARTMENT (423)751-8416 OR (423)751-2571 SHALL BE MADE BEFORE ANY SURVEY OR CONSTRUCTION WORK IS COMMENCED. BASE STATION FREQUENCIES AND TRANSFORMATION PARAMETERS WILL BE PROVIDED TO THE CONTRACTOR FOR USE IN CONSTRUCTION ACTIVITIES AT THE SITE. PREVIOUSLY USED OR ESTABLISHED CONTROL POINTS AND MONUMENTS SHALL NOT BE USED BY THE CONTRACTOR WITHOUT PRIOR APPROVAL BY TVA SURVEYING DEPARTMENT.

NOTES:

1. TOPOGRAPHIC MAPPING WAS GENERATED FROM A LIDAR SURVEY PERFORMED ON NOVEMBER 3, 2014, BY TUCK MAPPING SOLUTIONS, INC. AND SUPPLEMENTED BY HYDROGRAPHIC SURVEYS PERFORMED BY TVA ON SEPTEMBER 26, 2012 AND AUGUST 13, 2015, PROPOSED GRADING FOR THE DRAINAGE AND FLOW MANAGEMENT PROJECT (100%), AND SURVEY POINTS COLLECTED BY PHILLIPS AND JORDAN FOR THE KINGSTON ASH RECOVERY PROJECT AREA DURING CLOSURE ACTIVITIES.
2. CERCLA BOUNDARY CONSTITUTES BOUNDARY OF KINGSTON ASH RECOVERY PROJECT.
3. TOPOGRAPHIC MAPPING FOR FINAL GRADE WAS PROVIDED BY PHILLIPS AND JORDAN ON AUGUST 8, 2018.

NOTE:

100% DESIGN FOR THE DRAINAGE AND FLOW MANAGEMENT PROJECT (10W388 SERIES)(DCN 117580347) IS SHOWN ON THIS SHEET AND OTHER PLAN VIEWS. THESE ITEMS ARE SHOWN SCREENED REFLECTING THAT THEY WERE CONSTRUCTED AT THE TIME OF STILLING POND CLOSURE INITIATION.
